the overall system reliability, life, and LCC. The trade-off between the reliability of the component and its cost must be considered for proper selection of components and while ensuring their reliability. Likewise, once components are selected, they need to be configured in a specific arrangement among many alternatives in order to achieve an optimum system design that meets the requirements of the specification at minimum cost. The cost should of course take into account the cost of the components, maintenance, replacements, operation, and warranty over the expected life of the product. Once an optimum design is achieved, the product goes through the production process and is tested in order to ensure that it will meet its reliability objectives. Normally, all or a subset of accelerated testing, reliability demonstration testing, and **burn-in** testing are performed. The cost of testing could be detrimental to the launching of the product. Indeed, in some situations the cost of testing could exceed the total budget allocation for the product development, which might cause the termination of product entirely. The next step is to ensure that the product will function properly without failures or recalls for a specified period during which inspection and maintenance are implemented. The cost of spares at that time could be higher than the cost of replacement of the product with a new one. During this operation period of the product, **warranty policies** play a major role in extending or shortening the life of the product ownership.

As discussed, there are several phases in the product life cycle where reliability has a major impact on its cost. Therefore, we present these phases with a focus on the reliability and LCC during every phase. They are described subsequently.

LCC during Design Phase

Once a concept design of the product is developed, components are acquired and arranged or configured to meet the product functions. Selection of components has a major impact on the LCC of the product. For example, designing a nonrepairable product requires the selection of highly reliable components produced at stringent requirements and made from “prime” material to ensure that the components will not fail during the intended mission of the product. Such products include undersea fiber-optic cables where the product (cable) should not fail during an expected life of 70–80 years. Clearly, the failure rate

2 Life Cycle Costs and Reliability Engineering

of such components should be constant with very small values in the order of 1.0 FIT (FIT is a measure of failure rate and defined as one failure in 10^9 h). The cost and reliability of such components are relatively high, which results in lower operation cost (no failures and no down time) and the corresponding LCC values justify the use of the components. In this case, the cost of downtime and expected life without failure have indeed dictated the reliability of the components.

When the product or the system is repairable and the cost of down time and repairs are “acceptable”, the reliability of the components need not be as high as in nonrepairable systems. Therefore, the initial cost of the product will be significantly less than that of the nonrepairable product, but its operational costs are higher. The failure rates and the failure rate functions of the components are obtained from historical information or from extensive testing of the components at different operating conditions. Some industries and military standards provide information about the failure rates and design for LCC, see references [3–6].

The system configuration has a direct impact on its LCC. When the system is configured as a series system, i.e., the components are connected in series and the system fails when any of the components fails, then the operation and maintenance cost become more significant over the life of the system (product). Therefore, the total system cost of the system should be optimized to determine the optimum reliability levels of the components. The total cost is composed of the cost of the components (higher reliability components are more costly but decrease the downtime of the system), cost of repair, and downtime during the expected life of the system. Figure 1 shows the relationship between the **component reliability** level and the overall cost of the system. As shown, there is an optimum level that minimizes the overall cost [7].

Improving the series configuration might necessitate the introduction of **redundancy** of the components. When the system reliability is the main objective of the introduction of redundancy, then redundancy should be provided for the “weakest” component (least-reliable component) in the system. This can be achieved by having identical units or nonidentical units depending on the reliability of the component and the associated cost. This becomes an

Figure 1 Optimum reliability level

optimization problem with two objectives: maximization of the system reliability and minimization of the LCC, which should incorporate the maintenance cost (inspection, diagnostics, and repair) and the downtime cost. As the system becomes complex, the alternatives for system configuration increase and the computation of LCC is no longer simple. A simple formulation of the optimization problem is given as

$$\begin{aligned} & \text{Max } R(t) \\ & \text{s.t. } \sum_{i=1}^s c_i < C \\ & \sum_{i=1}^s w_i < W \end{aligned}$$

where $R(t)$ is the reliability function, c_i and w_i are the unit cost and unit weight, respectively, and C and W are the total cost and total weight of the system, respectively.

Other designs of the system configurations include **parallel systems**, series–parallel systems, parallel–series systems, and complex network configurations. Optimization of the design of parallel systems requires the determination of the optimum number of parallel components (each has its own reliability level or failure rate function and cost). The associated downtime, repairs, and warranty become difficult to calculate. Approaches have been developed to determine the optimum system configuration that maximizes the reliability (considered as a constraint in

the optimization problem) while minimizing the LCC, see for example [8–10].

In addition to the design of system configuration, designers are always faced with the problem of improving system reliability with minimum increases in cost. Sometimes, system design requires redundancies such as in power generation and number of engines of an aircraft. The latter is dictated by the aviation regulations, which states that no commercial aircraft should be designed with only a single engine. In such cases, both reliability and cost become an integral part of the system design and yet compete with each other.

Optimum allocation of components to the system configuration is indeed a challenging problem that does not have an optimum solution for large-scale systems but has a profound effect on the LCC. Heuristics for determining “good” solutions are developed using **genetic algorithms** and other meta-algorithms. One of the final tasks to be performed during the design phase is the reliability demonstration testing and reliability prediction testing. The costs associated with the test as well as its duration will impact the reliability estimate of the system and consequently its LCC. Longer test times will reveal potential failures of the system and will result in system improvement but it increases its LCC. Therefore, such reliability testing should be optimized with the objective of obtaining the most accurate reliability estimates at a minimum cost. A typical formulation of the test optimization problem is given in [11].

LCC during Production Phase

Once the product (system) is designed and its production begins, its reliability must be demonstrated throughout the production stage. A reliability demonstration test is performed to ensure that the product meets its reliability objectives as it is being manufactured. The test is also used to uncover unexpected failure modes or design errors. It is important that extensive testing be performed to avoid potentially expensive field failures which include all costs associated with product recalls, design fixes, and product repair. If a product failure results in personal injuries or catastrophic failures then the cost of settling lawsuits and litigation costs should also be included in the LCC. More importantly, customer awareness of the product reliability might indeed be detrimental

to the product market share. If any potential failure modes do escape to the field, the presence of a product support team, which includes failure analysis specialists, should be mobilized for rapid containment of any problem and removal of root causes responsible for reliability problems [12]. Clearly these have a significant impact on the system LCC.

There are two additional types of testing to be conducted before shipping the product; they are highly accelerated life testing (HALT) and burn-in testing. HALT is performed so that a product and the process that produces it are mature at the time of the product introduction (minimal, if any, **reliability growth** remains to be achieved), while design and development time are kept to a minimum [13]. HALT requires the application of two types of stresses individually, then simultaneously; they are thermal stresses and vibration step stresses. The stress levels are high in order to “discover” any potential latent defects or unexpected failure modes. The duration of the test and number of test samples add significant cost to the product development but might result in the reduction of potential field failures. This cost indeed adds to the overall LCC and the trade-off between the gain in product reliability due to this testing and the cost of the test as well as the delay in production need to be considered.

The second type of test is burn-in testing. This test is performed in order to “weed out” defective products due to poor assembly. The test is performed at stresses slightly higher than operating conditions so that the early failure rate region (infant mortality region) of the product is substantially reduced. In doing so, the repair cost as well as the recall cost of the product at its early operating hours is minimized. The duration of the test varies among manufacturers and products. Again, similar to HALT, the duration of the test has a major impact on the product life and LCC. Therefore, reliability engineers investigated different approaches for determining the optimum burn-in time. A simple model for estimating the optimum test time is described as follows.

Consider a product that has a Weibull failure time distribution β and θ as the shape and scale parameters of the distribution. Assume that we are interested in determining the optimum burn-in duration t . This can be obtained by expressing the total system cost as a function of the burn-in duration, warranty period, and field failures (if the test duration is too short, the

4 Life Cycle Costs and Reliability Engineering

system will exhibit high field failures). We define the following [14]:

- t : burn-in duration
- w : warranty period
- c_1 : burn-in cost per unit time
- c_2 : cost of a failure in the field during the warranty period
- c_3 : cost of a failure during the burn-in period
- β : the shape parameter of the Weibull distribution that represents the time to fail for the population
- θ : the scale parameter of the Weibull distribution that represents the time to fail for the population

The objective is to determine the optimum burn-in test period that minimizes the total system cost, which consists of the following three cost elements.

The system cost is the total of

1. the cost of conducting a burn-in test (tc_1);
2. the cost of units failed during burn-in (the probability of failing during burn-in, c_3); and
3. the cost of units failing during the warranty period in (the probability of failing during the warranty period, c_2).

Since the product's failure time follows a Weibull model with a **probability density function** of $f(t) = \beta/\theta (t/\theta)^{\beta-1} e^{-(t/\theta)^\beta}$, the reliability function is

$$R(t) = e^{-\left(\frac{t}{\theta}\right)^\beta} \quad (1)$$

The total system cost is

$$c_s = tc_1 + \left[1 - e^{-\left(\frac{t}{\theta}\right)^\beta} \right] c_3 + \left[1 - \frac{e^{-\left(\frac{t+w}{\theta}\right)^\beta}}{e^{-\left(\frac{t}{\theta}\right)^\beta}} \right] c_2 \quad (2)$$

The optimum burn-in duration is found by minimizing equation (2) in terms of t . To illustrate how the optimum burn-in duration is obtained, we use the example given in [14].

Example. Assume that the initial testing of the product shows that its failure time distribution is Weibull with a shape parameter of 0.8 and a scale parameter of 6000 days. The warranty period is 1000 days, and the average cost of a **warranty claim** is \$600. The cost of burn-in is \$0.09 per hour per product, and the cost of a failure during burn-in is \$4.00. Determine the optimum burn-in duration.

Solution. We use equation (2) after substituting the above values in the corresponding parameters. Thus, the system cost is expressed as

$$c_s = 0.09t + 4 \left[1 - e^{-\left(\frac{t}{6000}\right)^{0.8}} \right] + 600 \left[1 - \frac{e^{-\left(\frac{t+1000}{6000}\right)^{0.8}}}{e^{-\left(\frac{t}{6000}\right)^{0.8}}} \right] \quad (3)$$

Plotting the total cost of the system *versus* time results in Figure 2 with an optimum burn-in test duration of 30 h.

Extensive testing as described earlier during this phase of the product life cycle should reduce the overall cost of the product, and trade-off between the test cost and the field failure and repair cost must be carefully performed.

LCC during Operation Phase

The cost of the product during its operation phase includes the operating cost and more importantly its

Figure 2 Optimum burn-in duration

maintenance and repair cost. The latter cost requires the determination of optimum **preventive maintenance**, replacements, and inspection (PMRI) schedules. The term *optimum* arises from the fact that high frequency of PMRI increases the total cost of maintenance and reduces the cost due to the downtime of the system, whereas low frequency of PMRI decreases the cost of maintenance but increases the cost due to the downtime of the system. Hence, depending on the type of failure time distribution, an optimum PMRI may exist. Preventive maintenance may imply minimal repairs, replacements, or inspection of the components. Obviously there are systems where minimal repairs or inspections are not applicable, such as a microprocessor of a programmable logical controller. Similarly, the status of some systems can only be determined by inspection or testing—as in “one-shot” devices, such as military explosives. In this case, replacement is the only possible alternative.

The primary function of the preventive maintenance and inspections is to control the condition of the equipment and ensure its availability. Doing so requires the determination of the following:

- frequency of the PMRI,
- replacement rules for components,
- effect of technological changes on the replacement decisions,
- the size of the maintenance crew,
- optimum inventory levels of spare parts,
- sequencing and scheduling rules for maintenance jobs, and
- number and type of machines available in the maintenance workshop.

The above topics are a partial list of what constitutes a comprehensive PMRI [15]. Indeed the comprehensive maintenance during the operation phase of the product may result in added cost that exceeds

the initial acquisition cost of the product, which in turn increases the LCC of the product. The optimum maintenance (preventive or replacement) schedule is determined by minimizing the total maintenance cost of the product during its expected life (or cycle of operation) as demonstrated below.

The constant-interval replacement policy (CIRP) is the simplest preventive maintenance and replacement policy. Under this policy, two types of actions are performed. The first type is the preventive replacement that occurs at fixed intervals of time. Components or parts are replaced at predetermined times regardless of the age of the component or the part being replaced. The second type of action is the failure replacement where components or parts are replaced upon failure. This policy is illustrated in Figure 3 and is also referred to as *block-replacement policy*.

As mentioned earlier, the objective of the PMRI models is to determine the parameters of the preventive maintenance policy that optimize some criterion. The most widely used criterion is the total expected replacement cost per unit time. This can be accomplished by developing a total expected cost function per unit time as follows.

Let $c(t_p)$ be the total replacement cost per unit time as a function of t_p . Then

$$c(t_p) = \frac{\text{Total expected cost interval } (0, t_p]}{\text{Expected length of the interval}} \quad (4)$$

The total expected cost in the interval $(0, t_p]$ is the sum of the expected cost of failure replacements and the cost of the preventive replacement. During the interval $(0, t_p]$, one preventive replacement is performed at a cost of c_p and $M(t_p)$ failure replacements at a cost of c_f each, where $M(t_p)$ is the expected number of replacements (or renewals) during the interval $(0, t_p]$. The expected length of the

Figure 3 Constant-interval replacement policy

interval is t_p . Equation (4) can be rewritten as

$$c(t_p) = \frac{c_p + c_f M(t_p)}{t_p} \quad (5)$$

The expected number of failures, $M(t_p)$, during $(0, t_p]$ may be obtained using any of the methods discussed in [15].

Other maintenance policies that minimize the total cost over the life of the product are found in [15]. It should be noted that the above policy may include the cost of the spares, logistics, and others. However, these cost elements can also be included separately.

LCC and Warranty

A warranty is a contract or an agreement under which the manufacturer of a product or service must agree to repair, replace, or provide service when the product fails or the service does not meet the customer's requirements before a specified time (length of warranty). This specified "time" may be measured in calendar time units such as hours, months, and years, or in usage units such as miles, hours of operation, number of times the product has been used (number of copies made by a copier, number of pages printed by a printer etc.) or both. Other warranties have no specified "times" and are referred to as *lifetime warranties*.

Three types of warranties are commonly used for consumer goods: the *ordinary free replacement* warranty, the *unlimited free replacement* warranty, and the *pro rata* warranty. Under an ordinary free replacement warranty, if an item fails before the end of the warranty period, it is replaced or repaired at no cost to the consumer. The repaired or replaced item is then covered by an ordinary free replacement warranty with a period equal to the remaining period of the original warranty. Such warranty assures that the consumer will receive as many free repairs or replacements as needed during the original period of the warranty. The ordinary free replacement warranty is the most common type of warranty; it is most often used to cover consumer durables such as cars and kitchen appliances [16].

The second type of warranty, the unlimited free replacement, is identical to the ordinary replacement warranty except that each replacement item carries an identical warranty to the original purchase warranty. Such warranties are only used for small electronic

appliances that have high early failure rates and are usually limited to very short periods of time.

Thus, under the free replacement warranty, whether it is ordinary or unlimited, a long warranty period will result in a very large **warranty cost**. Furthermore, an increase in the warranty period will reduce the number of replacement purchases over the life cycle of the product, which consequently reduces the total profit of the manufacturer. Clearly, the free replacement policy is more beneficial to the consumer than to the manufacturer. Therefore, it is extremely important for the manufacturer to determine the optimal price of the product and the optimal warranty period such that the total cost over the product life cycle is minimized.

The third type of warranty is the *pro rata* warranty. Under this warranty, if the product fails before the end of the warranty period, it is replaced at a cost that depends on the age of the item at the time of failure and the replacement item is covered by an identical warranty. Typically, a discount proportional to the remaining period of the warranty is given on the purchase price of the replacement item. For example, if the period of the warranty is w and the item fails at a time $t < w$, the consumer pays the proportion t/w of the cost of the replacement items (automobile tires represent an ideal product for which the *pro rata* warranty policy is appropriate), and the manufacturer covers the remaining cost of the product replacement. Unlike the free replacement warranty, the *pro rata* warranty is more beneficial to the manufacturer than to the consumer.

As presented above, a pure free replacement warranty favors the consumer whereas a pure *pro rata* warranty favors the manufacturer. Therefore, a mix of these policies may present an alternative warranty, which is fair to both the consumer and manufacturer. For example, a policy that involves an initial free replacement period followed by a *pro rata* period is a sensible one, being fair to both the manufacturer and the consumer [17]. It has a promotional appeal to attract consumers and at the same time keeps the warranty cost for the manufacturer within a reasonable amount. There are other types of warranty policies such as reliability improvement warranty where the manufacturer provides guaranteed mean time between failures (MTBF) or provides support for engineering [18].

Clearly, warranty cost is an added cost to the product life cycle and it should be minimized by

improving the reliability of the product during all phases of its life cycle. Recent effort by one of the leading automakers in reducing its warranty cost and extending the warranty period resulted in a significant increase of its sales.

Warranty Claims and Costs: Statistical Analysis of

Introduction

Warranty is inherently business related, but the topic, and particularly the data arising from warranties, has generated tremendous interest in the academic literature. This article will refer mainly to books and survey papers, but interested readers should consult the references therein for additional details.

The type of data analysis performed in practice depends on the business purpose and also on the nature of the available data. The data itself generally exists to serve some business purpose, not necessarily identical to the purpose of the proposed analysis. For example a listing of warranty claims for repairs performed for customers may exist primarily to allow the manufacturer to pay dealers for their service, but the same data may be used to estimate the reliability of the product in the field or to estimate the extent of future claim payments. Also, the available data depends on the nature of the warranty coverage. For example, repairs made outside of the warranty coverage period may not be available to the manufacturer.

A warranty has been described as a contract between the buyer and the manufacturer, and it protects both parties. Murthy and Djameludin [1] offer this definition as well as theories for the study of warranty including the theory that warranties provide a signal of reliability to the customer and also the investment theory that a warranty is in effect an insurance policy for the customer. Robinson and McDonald [2] list business facets impacted by warranty including warranty as a product attribute, which seems especially important today. Buyers may value generous warranties in addition to attractive features, and both of these will usually add cost for the producer. Sellers of relatively unknown brands may reduce the uncertainty of a prospective buyer with a generous warranty.

Two basic types of warranty coverage are free replacement and *prorata*. Free repair is similar to free replacement, but may dictate different modeling assumptions for a complex system such as an automobile. Some warranty coverages are two dimensional,

as with age and mileage for automobiles. Warranties between two businesses or those involving government contracts often have specialized features to encourage the seller to improve reliability. See Blischke and Murthy [3] for extensive discussions on these topics.

Regardless of the type of coverage the warranty database will generally have uses beyond its basic purpose as a financial record. The database usually includes a list of records of repairs or other services performed for the customer by the manufacturer or on its behalf. These records constitute a “claim” against the manufacturer. The potential for new claims, either from units in the field or those yet to be sold, represents a future liability. Estimating the extent of the future liability is a business requirement.

The available data may include much more than just a list of claims. Claims may be linked in the database to sales records, customer information, production records, information from surveys, etc. The extent and detail of this auxiliary information will determine the options for statistical analysis. For example, if detailed sales records are available, then the time in the field or current “age” for every unit is known. If the sales records can be linked to the claims records, then the age of any unit at the time of a claim is also known, permitting what has been called *age-based* warranty analysis. Model and option information from sales records as well as production information may allow stratifying the analysis to enable comparisons across models, plants, or suppliers. Other data limitations and specialized analyses are discussed in the last section.

Statistical Models

The age or time of occurrence of warranty claims can be considered a type of reliability data, and many reliability models can be applied to warranty data. One approach is to regard warranty claims as events from a **repairable system**, where counting processes play a prominent role. Let $N_i(t)$ be the number of claims that have occurred through time t on unit i , and let these be modeled by a counting process. A fundamental quantity, both in theory and for practical work, is the *mean cumulative function*, $\Lambda(t) = EN_i(t)$. Means are important in practice for warranty analysis because totals are important. We may prefer nonparametric approaches for estimating the mean

2 Warranty Claims and Costs: Statistical Analysis of

cumulative function, especially if the number of units is large.

Nonhomogeneous **Poisson processes** form a class of models that would naturally apply if the claim corresponds to a “**minimal repair**”, i.e., the unit is assumed to be restored to its state prior to failure. If the claim corresponds to a repair that is assumed to restore the unit to its original state or if the claim corresponds to a replacement of the unit, then the class of **renewal processes** may apply. Note that replacement of a failed component in the unit is not the same as replacement of the unit itself. The former is essentially a repair and would not ordinarily be expected to restore the unit to its original condition.

If the number of claims for a unit is nearly always zero or one, then methods from lifetime data analysis are applicable, either parametric or nonparametric. The lifetime distribution of the time to first repair or replacement is of fundamental interest. See Meeker and Escobar [4], Rigdon and Basu [5], Lawless [6], Kalbfleisch and Prentice [7], and other general references on statistical models for reliability and lifetime data for detailed methods.

One feature that distinguishes warranty data in particular from reliability data in general is the presence of costs, which usually occur along with the time of the claim in a warranty database. This is a complication, but costs can often be modeled separately from the rate of accumulation of claims. If so, then simply note that for a given unit, cost equals number of claims times average cost per claim. Then separate these two elements in the analysis. In addition to the claims arrival process, also model the distribution of costs per claim, which may require some degree of stratification. Another approach is to view the cost as a “mark” associated with the claim and apply the class of marked counting-process models. Finally, nonparametric approaches to estimating the mean cumulative function work equally well for amounts (costs) as they do for counts (number of claims), which eliminates the need for a separate model for costs. See Nelson [8] for details on the nonparametric approach.

Statistical Analysis

As indicated in the last section many reliability models can be applied to warranty data. This section emphasizes issues and analysis approaches that relate

to some of the special characteristics of warranty data. We begin with a brief discussion of warranty data in the context of sampling and warranty claims as distinct from failures. This is followed by a more detailed automotive example to illustrate that warranty analysis should account for the coverage limitations of the **warranty policy**. The section concludes by discussing briefly a few of the other specific problems and approaches that arise with warranty data.

Not Samples and Not Failures

Warranty data do not usually constitute a random sample, so strictly speaking the assumptions required for, say, **confidence intervals** do not apply. However, in practice we may be willing to treat, say, the collection of first units sold as though it were a statistical sample representing all the units that will eventually be sold. But inference should proceed with caution and, if possible, use the data itself to check for evidence of **bias**.

Warranty claims do not necessarily correspond to failures. Manufacturers may cover some warranty repairs or replacements for customers as a goodwill gesture even though in the manufacturer’s view the unit has not failed. If the goal is to estimate warranty costs for example, then we might proceed with analyzing the data as it is with the understanding that claims represent not just failures but also other forms of dissatisfaction that may lead a customer to seek recourse under a warranty agreement. However, if the goal is to estimate the actual failure rate in the field, then some screening or further analysis of the claims may be necessary before submitting the data to an analysis based on methods from reliability theory.

Warranty Coverage Example: Automotive Data

As mentioned in the introduction, warranty data is limited by the nature of the warranty coverage. This is an extremely important feature that must be considered in order to properly analyze the data. Consider for illustration automotive warranty coverage. Since detailed sales information is available, it is reasonable to analyze the data by vehicle age, which is defined by the time that has passed since the vehicle was sold as new. But automotive warranties are typically limited by mileage as well as age, so the warranty data will not include repairs made on vehicles that have

exited warranty coverage due to the mileage limit, even though they are within the nominal age limit. This example is complicated further by the fact that, unlike ages, which are known all the time for all vehicles, mileages are only known for vehicles that generate a claim, and then only at the time of the claim because the odometer reading is only recorded at the time of the claim.

The issue illustrated here is similar to what occurs in epidemiology. We need to know or to estimate the number of units (people in epidemiology) that are at risk. The number at risk is the denominator in a claim rate calculation. In warranty analysis the denominators are often harder to obtain than the numerators, which typically come directly from the claims. Continuing with the automotive example, the number of claims for vehicles of age t can be obtained readily from the claims data. In an analysis that ignores mileages, the corresponding denominator would simply be the number of vehicles that are currently age t or older, which we could write as $\sum I(a_i \geq t)$, where a_i is the current age of vehicle i , $I(\cdot)$ is the indicator function, and the summation is over all vehicles under observation. Ignoring the complication of missing mileage information, a denominator adjusted for mileage coverage would be $\sum I(a_i \geq t)I(M_i(t) \leq L)$, where $M_i(t)$ is the accumulated mileage of vehicle i at age t , and L is the warranty coverage limit for mileage.

Figure 1 illustrates the mileage example. For the details see Chukova and Robinson [9]. The plot displays the estimates of the mean cumulative function of cost as a function of age, first ignoring mileage (bottom curve) and then adjusting the number of vehicles at risk for mileage accumulation (top curve). Note that both estimates may serve a purpose. The bottom curve displays how warranty expenses actually accrue as a function of age. The top curve estimates how they would accrue in the absence of a mileage limit and may be more appropriate for engineering analysis.

Other Special Types of Warranty Analysis

The previous example illustrates one of many special circumstances that can occur in the analysis of warranty data. Some of the others are discussed briefly in this subsection. For more details, see Karim and Suzuki [10] and the collection of papers in Blischke and Murthy [11]. Jerald Lawless and his coauthors

Figure 1 Mean cumulative function of cost by age with and without adjustments for mileage

have made a number of important contributions to warranty analysis; see Lawless [12] and the references therein. Chukova *et al.* [13] provide a survey of warranty analysis and references to work that has appeared in eastern European journals.

Reporting delays can influence warranty data and the resulting analysis. Neither claims nor sales information may be recorded in the database immediately. Solutions involve adjusting the number of units at risk using the observed distribution of delay times.

The automotive mileage example illustrated a case of dual usage measures, age and mileage, but the analysis described before was essentially univariate. However, fully bivariate approaches have been developed, particularly for the case where renewal processes apply. Also, the problem of incomplete mileage information (or any secondary usage measure) can be handled by using supplementary sample data. This would happen in the automotive example if mileage accumulation information were available, say from **survey data**. Not all warranty analysis is age based. Sometimes the data to support it may not exist because sales or warranty claim information is incomplete or cannot be cross-referenced. Nevertheless, some analysis methods have been developed for specific problems where the models are tailored to the specific data that are available. For example, Karim

and Suzuki [10] refer to “marginal counts” analysis, where the available information consists only of the number of units sold and the number of warranty claims by calendar month. This survey article contains a number of important references to articles on this topic and to the others discussed in this section.

Warranty analysis by covariates can be useful. The **covariate** effect may refer to the product, perhaps the model or vintage, or it may refer to the customer who bought the product, or where the item was purchased. In practice, covariate analysis is probably most often accomplished simply by doing separate analyses for the various cohorts of interest, but covariate effects can often be modeled rather easily, particularly with Poisson models.

Since parametric models allow one to extrapolate, they are natural choices to create forecasts of future warranty costs or claim rates. Of course, all the usual warnings associated with extrapolation apply. In practice there may be archives of warranty records for past products that are the same, or similar with respect to warranty trends as the current models. Using the past data can help offset the risk associated with extrapolation. This topic does not appear to have been discussed extensively in the literature. Likewise, **Bayesian approaches**, which would tend to incorporate past data rather naturally, have received little attention. One exception is Chen *et al.* [14], which takes a Bayesian approach and also discusses using past data.

Warranty data analysis can also play a role in **quality monitoring**. Wu and Meeker [15] describe a process for monitoring a warranty database to provide an early warning of reliability problems. They adopt a Poisson model and report warranty claim rates as they would be monitored in calendar time and also as a function of vehicle age, time of production, and the type of service operation. They formulate a multivariate model and a hypothesis test to detect increasing rates, a key feature of which is the management of an overall false alarm rate.

In summary, warranty claim occurrence data can be analyzed as reliability data. Handling cost per claims may require additional analysis. However, the analysis should account for the many special features of the data such as data limitations caused by coverage limits. Due to technology enhancements warranty data are likely to become more extensive, more frequent, more complex, and linked to more

nonwarranty data sources than ever before, thereby offering considerable challenges for future analysis.

Warranty: Usage and Wear Process for

Introduction

A warranty is a contract that requires the manufacturer of a product to repair or replace it if it fails. Several other articles in this encyclopedia discuss warranties and I refer you to these for a more detailed definition (*see* **Multiattribute Warranty Policies; Warranty Cost Prediction Based on Warranty Data**). This chapter discusses the issue of wear, or usage, of a product subject to a warranty. The goals of the chapter are to motivate why one should consider wear in the context of warranty analysis, describe probability models for wear processes, show how models for the lifetime of a product can be related to the amount of wear it has undergone and finally discuss how to apply these ideas to solve problems related to warranty analysis.

Warranty analysis is concerned with solving the problems surrounding warranties. These include determining the optimal warranty period, estimating the cost of a **warranty policy**, and forecasting future **warranty claims**. The computation of the cost of a warranty depends on the lifetime of the product, which is an uncertain quantity. So an important aspect of warranty analysis is to propose probability models for the lifetime of a product. Warranties are discussed extensively in this encyclopedia (*see* **Warranty Claims and Costs: Statistical Analysis of; Multiattribute Warranty Policies; Warranty Modeling; Warranty Cost Analysis; Warranty Cost Prediction Based on Warranty Data; Warranty Servicing**).

Many products for which warranties are offered operate in a dynamic environment that will vary in a random manner over time and that will affect the lifetime of the product. A convenient way to think of the effect of the environment is that it ages or induces “wear” on the product. Often such wear can have a physical interpretation, for example, on a vehicle, wear may refer to kilometres driven and in this case the warranty period may even be defined in terms of it. So a convenient approach to warranty analysis is to propose models for the accumulation of wear on the product. The wear process defines a model for time to failure. The wear process is used directly

if the warranty period is also defined in terms of use.

Wear processes are naturally modeled as stochastic processes. A warranty pertains to future failures of a product when it is taken out; the exact nature of the wear that the product will experience is unknown and varies with each sample sold. A deterministic model cannot easily capture these properties of wear while random processes can.

We note here that these ideas have much in common with the idea of degradation models and **random environments** and cumulative damage models (*see* **Degradation Models; Cumulative Damage Models Based on Gamma Processes**, respectively).

This chapter is organized as follows. The section titled “Wear Processes” defines different stochastic processes that can be used to model the accumulation of wear on a product. Broadly speaking, these models are described in the order of complexity from the simplest (the **Poisson process**). The section titled “Using Wear Processes in Warranty Analysis” shows how these models are incorporated into a model for the time to failure of a product and gives examples of applications to warranty analysis.

Wear Processes

We will always consider models that describe the cumulative amount of wear that a product accumulates, rather than the rate of wear. The goal is to define a model for how much wear a product has accumulated at any time. We let $W(t)$ denote the amount of wear at time t .

Any process that we define for $W(t)$ should satisfy $W(0) = 0$. At the time the product is bought, it is considered new and has no wear associated with it. Also, $W(t)$ should be positive; it makes no sense to talk about negative wear. One might further restrict $W(t)$ to be nondecreasing. This depends on whether $W(t)$ models the rate or intensity of wear at t , in which case $W(t) \geq 0$ is sufficient, or models the cumulative amount of wear by t , in which case we impose $t_i < t_2$ implies $W(t_1) \leq W(t_2)$. Here we discuss nondecreasing $W(t)$, so that it is the cumulative amount of wear. However, what we have to say in the section titled “Using Wear Processes in Warranty Analysis” is also valid where $W(t)$ is the rate of wear.

2 Warranty: Usage and Wear Process for

Poisson Processes

These are the most common stochastic processes satisfying our two properties for $W(t)$. It is a process that starts at zero and at random intervals of time increases in value. The times between successive increases are independent. Poisson processes are discussed in detail in **Poisson Processes** so we give only a summary here.

All Poisson processes are defined in terms of a function $\lambda(t)$ called the intensity or rate function. At any time t , the probability that the process increases value in a small interval of time δt is approximately $\lambda(t) \delta t$. The process has the property of independent increments: the increase in the process in nonoverlapping time intervals are independent.

In the (simple) Poisson process, each increase in value is always 1. The probability distribution of $W(t)$ is Poisson:

$$P(W(t) = n) = \frac{\Lambda(t)^n}{n!} e^{-\Lambda(t)}, \quad n = 0, 1, \dots \quad (1)$$

where $\Lambda(t) = \int_0^t \lambda(s) ds$. In **Intensity Functions for Nonhomogeneous Poisson Processes**, different intensity functions $\lambda(t)$ are discussed.

Poisson processes are easy to work with because the distribution of $W(t)$ is of a simple form. As a model for wear, they are suitable when the wear takes the form of a count of events; the number of times a light bulb is switched on is one example. However, it is clear that we need more complicated processes to model most types of wear that interest us.

A useful generalization is to allow the value of the process to jump at each event by a random amount, rather than letting it always be 1. If the increases are independent and identically distributed then we have the compound Poisson process. A good reference is Chapter 5 of [1], where the probability distribution function is derived. It is often possible to compute the probability density function of $W(t)$, for example, when the increases have a stable distribution, as described in [2]. If the X_i are exponentially distributed with a mean μ , where $f_X(x) = \mu^{-1} e^{-x/\mu}$, it can be shown that:

$$P(W(t) = 0) = e^{-\Lambda(t)} \quad (2)$$

$$f_{W(t)}(w) = w^{-1} e^{-\Lambda(t) - w/\mu} \sum_{i=1}^{\infty} \left(\frac{w \Lambda(t)}{\mu} \right)^i$$

$$\times \frac{1}{i! (i-1)!}, \quad w > 0 \quad (3)$$

A compound Poisson process can model usage that accumulates as randomly sized shocks, such as satellites subject to solar storms of varying magnitude. Figure 1 shows realizations of the homogeneous, nonhomogeneous, and compound Poisson processes.

Other generalizations of the Poisson process are possible: these include the doubly stochastic Poisson process, which is a Poisson process where the **intensity function** is itself random and the self-exciting point process, where the intensity function depends on the history of the process. The self-exciting point process has practical application to situations where the current usage of an item depends upon its past usage; for example, if a machine undergoes a period of heavy use, the user may then decide to let the machine stay idle for sometime in order to perform maintenance. If the period of heavy use does not occur, the machine is kept running. The reader is referred to [3, Chapter 5] for a detailed description of self-exciting point processes, but it is mentioned that, as with doubly stochastic Poisson processes, the density of $W(t)$ is in general difficult to find.

The Gamma Process

For many types of wear the increases are more continuous in nature than the Poisson process can model. The gamma process is an independent increments process that increases continuously. The idea is that the increase in the value of the process between any two times is gamma distributed, with the mean value of the increase becoming larger as the two times are further apart. Gamma processes are discussed in more detail in **Cumulative Damage Models Based on Gamma Processes**.

Recall that the gamma distribution density function is defined by two parameters: a scale parameter a and a shape parameter b :

$$f(w | a, b) = \frac{a^b}{\Gamma(b)} w^{b-1} e^{-aw}, \quad w \geq 0 \quad (4)$$

where $\Gamma(b)$ is the gamma function; the mean of the gamma distribution is b/a . In a gamma process, the shape is a nondecreasing and continuous function of time $b(t)$ with $b(0) = 0$. For two times $t_2 > t_1$, the distribution of $W(t_2) - W(t_1)$ is gamma with scale a and shape $b(t_2) - b(t_1)$. The mean of $W(t) - W(s)$ is

Figure 1 Realizations of three wear processes. Clockwise from top left: a homogeneous Poisson process with $\lambda(t) = 4$; an intensity function $\lambda(t) = 4$ if $\lfloor t \rfloor$ is even, $\lambda(t) = 0$ otherwise; a nonhomogeneous Poisson process with this intensity function; a compound Poisson process with this intensity function and exponentially distributed jumps with a mean of 1

then $(b(t_2) - b(t_1))/a$. The gamma process has been rigorously studied; see, for example, [4] or [5], and generalizations discussed in [6].

The gamma process is clearly suitable for modeling the wear of a system that is in continuous use. The increase in the value of the process varies randomly; that can model the fact that the system is subject to varying amounts of stress as it is used.

Markov Additive Processes

Many systems accumulate significant wear only part of the time rather than always; any system that is not used all the time, or switched on and off, will clearly accumulate wear at a much higher rate when used than not.

It is difficult to model such a situation with a gamma process. However, we can think of a wear process that sometimes acts like a gamma process (system being used) and other times stays constant (system not being used and no wear being accumulated). Çinlar has described a set of processes like this called Markov additive processes [7]. In such

a process, $W(t)$ is defined in terms of a state $S(t) \in \{0, 1\}$, where 0 represents off and 1 represents on. Switches between on and off occur at random times that are independent and exponentially distributed amounts (this is an example of what is called a Markov process). When $S(t) = 1$ then $W(t)$ increases like a gamma process. When $S(t) = 0$ then $W(t)$ stays constant.

To define such a process we need to define: the mean time switched on and the mean time switched off (these are sufficient to define the exponential distribution for the length of each on and off period) and the parameters a and $b(t)$ of the gamma process.

One nice property of this idea is that it generalizes in many useful ways. We can replace the gamma process with any other process for wear that we want. When $S(t) = 0$ we do not have to have that $W(t)$ as a constant but can allow it to increase according to another process, so allowing the system to accumulate some wear even when switched off. Also $S(t)$ can have more than two states; for example, we can define states that represent high, median, and low stress as well as off, then define a suitable wear process for

Figure 2 An example of a Markov Additive Process. (a) The state process $S(t)$ and (b) a corresponding process $W(t)$ that is a gamma process when $S(t) = 1$ and does not change when $S(t) = 0$

each. Also allowed is a “shock” to the value of $W(t)$ when it is switched on. For example the wear on a car engine in the first minutes after being switched in is considerable. Figure 2 shows a typical realization for the simple form of this process, where $S(t)$ is 0 or 1, with no wear accumulating when $S(t) = 0$ and wear accumulating as a gamma process when $S(t) = 1$.

Çinlar explores the properties of these processes in detail in [7]. Other references of note are [8] and [9], which describe similar classes of processes that can be used to model usage as a continuous, nondecreasing process.

Although the set of Markov additive processes is very general and contains processes that seem to reasonably describe many types of wear, this is at the expense of tractability, and most of the results concerning these processes are characterization results and not explicit formulations of the density of $W(t)$. In some cases, however, one is able to describe the density function of $W(t)$. For example, let $W(t)$ be a Markov additive process with an active and idle state $S(t) \in \{0, 1\}$. Let $G_1(t)$ be a gamma process with scale parameter a and shape function $b(t) = bt$ and assume no wear occurs when idle, so $G_0(t) = 0$.

We start by defining $W(t | \{S(u), 0 \leq u \leq t\})$ as the process $W(t)$ conditional on knowing the entire history of the state to time t . We show in [10] that $W(t | \{S(u), 0 \leq u \leq t\})$ is gamma distributed with scale a and shape function $b(s) = b \int_0^t S(s) ds$; thus $b(s)$ is simply b multiplied by the amount of time to t that the system is working. We then show how to use this to approximate the **probability density function** of $W(t)$.

Using Wear Processes in Warranty Analysis

In this section, I will discuss one way in which wear processes can be used in warranty analysis, namely to define a joint distribution of the time and usage at failure of the item. All of this is described in much more detail in [11] and [10], which we refer you to for details that we skip below.

This is relevant for warranties that are defined in terms of the wear as well as time, for example, in automobiles, if wear is defined as distance traveled. The earliest use of this idea is [12], who used it to

look at the optimal replacement policies for items subject to wear.

Let T and W be the time and wear at failure of the item. Let $f_{T,W}(t, w)$ be the probability density function of time and wear at failure. Then we can write by the multiplication law of probability $f_{T,W}(t, w) = f(t | w) f(w)$. Now w must be the wear at time t and so:

$$f_{T,W}(t, w) = f(t | W(t) = w) f_{W(t)}(w) \quad (5)$$

where $f(t | W(t) = w)$ is the probability density of failure at time t given the wear at that time and $f_{W(t)}(w)$ is the density function of the amount of wear at time t . The density function $f_{W(t)}(w)$ comes from the wear process model i.e., it is a Poisson distribution if $W(t)$ is a Poisson process, etc.

A simple model for $f(t | W(t) = w)$ is to say that the failure rate $r(t)$ of the item is an increasing function of the amount of wear that it suffers; simple forms for $r(t)$ might be $r(t) = r_0(t) + aW(t)$ or $r(t) = r_0(t)e^{aW(t)}$, with $r_0(t)$ the baseline failure rate under no wear and $a > 0$. I take the first form in what follows. Recall that the reliability function is $P(T > t) = \bar{F}(t) = \exp(-\int_0^t r(s) ds)$ and $f(t | W(t) = w) = -d/dt \bar{F}(t | W(t) = w)$, hence:

$$\begin{aligned} \bar{F}(t | W(t) = w, W(s), 0 \leq s \leq t) \\ = \exp\left(-\int_0^t r_0(s) - a \int_0^t W(s) ds\right) \end{aligned} \quad (6)$$

So the reliability depends on the integrated wear $\int_0^t W(s) ds$ given $W(t) = w$, which we denote as $\mathcal{W}(t)$. This is a random quantity just like $W(t)$. The reliability $\bar{F}(t)$ unconditional on $\mathcal{W}(t)$ is what we want and in [10] we show how this can be done. One example that produces a nice mathematical form for $f(t | W(t) = w)$ is if $W(t)$ is a Poisson process with intensity function $\lambda(t)$. Defining $R_0(t) = \int_0^t r_0(s) ds$ to be the cumulative baseline hazard, we show that:

$$\begin{aligned} f(t | W(t) = w) \\ = (r_0(t) + aw) e^{-R_0(t)} \Lambda(t)^{-w} \\ \times \left[\int_0^t \lambda(s) e^{-a(t-s)} ds \right]^w \end{aligned} \quad (7)$$

and hence the joint density function of time and wear at failure is:

$$\begin{aligned} f_{T,W}(t, w) = \frac{r_0(t) + aw}{w!} e^{-R_0(t) - \Lambda(t)} \\ \times \left(\int_0^t \lambda(s) e^{-a(t-s)} ds \right)^w \end{aligned} \quad (8)$$

If $W(t)$ is homogeneous (with $\Lambda(t) = \lambda t$) and $r_0(t) = r$ then we have

$$f_{T,W}(t, w) = \frac{r + aw}{w!} \left(\frac{\lambda}{a} (1 - e^{-at}) \right)^w e^{-(r+\lambda)t} \quad (9)$$

for $t \geq 0$ and $w = 0, 1, 2, \dots$

Figure 3 shows two examples of equation (9) for different values of the wear rate parameter λ , where we see that as λ increases there is higher probability on failures at an earlier time but with more wear.

Finally, we note that by integrating out w in equation (8) we obtain the density of time to failure alone, which can be used in applications where time is the only warranty measure. In the case of equation (9), it turns out that this gives us a reliability function:

$$\bar{F}(t) = \exp\left(-(r + \lambda)t + \frac{\lambda}{a}(1 - e^{-at})\right), \quad t \geq 0 \quad (10)$$

Applications

For warranties, the derivation of $\bar{F}(t)$ or $f_{T,W}(t, w)$ is only half the story. These distributions must then be used to solve a warranty-related problem. Space does not permit a description of these here but the reader is referred to [10], where there is a discussion on how to produce an optimal warranty size for a product, given data on when it failed and with how much use. A similar problem is solved in [13], although the wear process model there is not a stochastic process. The reader is also referred to [14] which describes several problems associated with warranties where a probability model for time and usage to failure is part of the solution.

Multiattribute Warranty Policies

Introduction

Nearly everything sold in the market is covered by a warranty – expressed or implied. Various types of warranties serve a number of purposes, including protection for the buyer against low quality or service and limitation of product liability for the seller. In some instances, warranties are mandated and regulated by state and local governments. Because of this diversity of purpose, warranties have been studied by researchers in many different disciplines, such as engineering, management, marketing, economics, law, and accounting. For more details of warranty applications, see **Warranty Servicing**.

A warranty is a seller's guarantee given to the buyer stating that a product is reliable and free from known defects and that the seller will repair or replace the product if it fails to conform to satisfactory performance. Consequently, this obligation generates costs to the producer associated with failures of the product. Thus, one of the decision problems faced by producers in warranty analysis is how to compare various types of warranty plans and estimate the total cost associated with each plan.

A formal development of warranty models can be traced back to a paper by Arrow [1]. Since then, a wide variety of warranty policies has been proposed and various statistical models for determining warranty costs have been developed. Now one can say that warranty analysis constitutes a "field" of study within engineering–statistics–marketing. As further evidenced by a series of review papers by Blischke and Murthy [2] and Murthy and Blischke [3, 4], and a handbook edited by Blischke and Murthy [5], this particular field of study has experienced a rapid growth and extensive applications to various managerial decision problems.

In this note, we first classify various types of warranty plans proposed in the literature, and then review several methods of modeling two-attribute warranty policies. For further development of warranty models and analysis methods, readers are referred to Thomas and Rao [6] and Murthy and Djamaludin [7]. For articles in this encyclopedia that are related to the

analysis of warranty policies see the section titled "Related Articles".

Warranty Policies

A warranty can be thought of as a contractual *obligation* or a potential *liability* to the seller. However, the limit of the seller's obligation or liability is usually specified at the time of product sale and the seller is responsible only for the product failures satisfying the prespecified warranty criteria. On the basis of the number of warranty attributes used in determining the warranty eligibility, warranty plans can be classified as (a) *single-attribute* warranty policies and (b) *multiattribute* warranty policies.

In *single-attribute* warranty policies, we use only one of the warranty characteristics, such as the time, the hours of operation, the mileage, or the frequency of product usage. The most popular criterion is the *warranty period* that is measured from the time of sale of the product to a certain point in the product's lifetime. The popularity of the warranty period is twofold. In most instances, the total number of product failures is a function of time. Besides, time is easily measurable and thus tends to minimize potential conflicts between a seller and a buyer on the warranty eligibility of a failed product.

In *multiattribute* warranty policies, on the other hand, more than one warranty characteristics are employed simultaneously as criteria in judging the warranty eligibility of a failed product. Under the 5-year, 50 000-mi protection plan used in the automobile industry, for instance, the warranty eligibility of an automobile is determined by its age and mileage at the time of breakdown. Since its introduction in the late 1960s, the two-attribute warranties have become a critically important segment of the automobile business environment.

It is reported that aircraft manufacturers also offer this type of two-attribute warranty policy, with usage corresponding to the number of flying hours. In the next section, we review various types of single-attribute warranty policies.

Single-Attribute Warranty Policies

Under the typical situation of a single-attribute warranty transaction, a seller provides some kind of repair or replacement service for any product

2 Multiattribute Warranty Policies

failures occurring during some specified time. For the warranty service, a buyer pays either no cost or a pre-determined portion of the full repair or replacement cost. Therefore, two of the major decision variables in a single-attribute warranty policy are the *warranty price* and the *warranty period*: (a) *how much* a buyer should pay to receive the warranty service and (b) *how long* a seller should provide the warranty service.

On the basis of the nature of a buyer's payment of repair or replacement cost upon a product failure, warranty policies can be divided into (a) the free-replacement warranty, (b) *pro rata* warranty, and (c) lump-sum warranty. First, under the *free-replacement* warranty policy shown in Figure 1(a), a producer provides as many replacements or repairs as needed free of charge to a consumer as long as the product failures satisfy the warranty criteria. In many cases, the anticipated cost of honoring the free warranty service has already been included in the selling price of the product or put into reserve to meet future **warranty claims**.

Second, under the *pro rata* warranty (or rebate) policy, a consumer must pay a fraction of the full repair cost. As shown in Figure 1(b), the fraction is usually determined by the percentage of the warranty period in use by the old item prior to the failure. An automobile tire typically carries such a *pro rata* warranty, in which a buyer pays a small portion of the full replacement cost on the basis of the remaining tread depth or the mileage driven.

Third, under the *lump-sum* warranty policy shown in Figure 1(c), a customer receives a fixed or lump-sum rebate for any product failures occurring within the warranty period. Particularly when it is difficult to measure the exact time of product failure, this policy is employed to minimize potential conflicts

between a producer and a customer about the amount of compensation due for product failure.

We can also imagine a hybrid form of the aforementioned warranty policies. As shown in Figure 1(d) for example, a total warranty period can be divided into two periods: an initial free-replacement warranty period, followed by a *pro rata* period.

On the basis of how long a producer should provide the warranty service, warranties can be classified as (a) fixed-period and (b) renewable policies. First, under the *fixed-period* warranty policy, the warranty period is specified at the time of product sale and fixed regardless of a producer's repairs or replacements. The warranty terms expire automatically at the end of the warranty period. This type of warranty policy is the most popular in practice.

Second, in the *renewable* warranty policy, the original warranty period is extended whenever a repair or replacement occurs during the current warranty period. When the current warranty period expires without any product failures, the warranty terms expire completely. Renewal theory, described in **Renewal Theory**, can be applied to describe this failure process if we assume that successive failure times form a renewal reward process.

We can imagine different types of multiattribute warranty policies but, in the next section, we restrict our attention to the two-attribute warranty policies, which is the most common in practice. For more technical presentations of warranty models, readers are referred to **Warranty Modeling**.

Multiattribute Warranty Policies

As shown in Figure 2, various types of two-attribute warranty policies have been considered in literature: (a) rectangular, (b) triangular, (c) L-shaped, and (d) parabolic warranty policies. The 5-year, 50 000-mi automobile warranty can be displayed in a *rectangular* form as in Figure 2(a); any breakdowns of an automobile will be eligible for the warranty service as long as its age is less than x^* years and its mileage is less than y^* mi. In terms of set notation, the region covered by the warranty is denoted by $\Omega = \{(X, Y) \text{ for } X < x^* \text{ and } Y < y^*\}$.

In the *triangular* warranty policy, on the other hand, the warranty region is expressed as $\Omega = \{(X, Y) \text{ for } aX + bY < c\}$, where a, b , and c are

Figure 1 Various types of single-attribute warranty policies

Figure 2 Various types of two-attribute warranty policies

constants specified by a seller at the time of product sale. We can also imagine the *L-shaped* warranty policy as shown in Figure 2(c), in which the product is eligible for the warranty service if X is less than x^* or Y is less than y^* ; i.e. $\Omega = \{(X, Y) \text{ for } X < x^* \text{ or } Y < y^*\}$.

Since the product failure is a function of X and Y , the ISO **warranty cost** curve can be drawn on the plane for a given cost as shown in Figure 2(d). Moskowitz and Chun [8] proposed such a *parabolic* warranty policy, in which the producer offers a set of warranty plans for the same price and each customer can choose any plan in the set. For example, the producer may offer $\Omega = \{(2 \text{ years, } 100\,000 \text{ mi}), (5 \text{ years, } 50\,000 \text{ mi}), (8 \text{ years, } 30\,000 \text{ mi})\}$. In such a case, a retired grandmother would prefer the 8-year, 30 000-mi warranty policy, whereas the 2-year, 100 000-mi plan is appealing to a traveling salesman. While any other type of two-attribute warranty policy tends to favor one group of consumers over another, the parabolic warranty policy is shown to be more equitable to all consumers.

Chun and Tang [9] analyzed the relationships among the aforementioned two-attribute warranty policies. They also showed that the single-attribute warranty policies are special cases of two-attribute policies.

Modeling Two-Attribute Warranties

Offering warranty coverage leads to additional costs to the producer, associated with claims under warranty. Thus, a producer needs to estimate the expected total cost of offering a two-attribute warranty policy. Various approaches have been proposed in modeling two-attribute warranty policies: (a) two-dimensional, (b) one-dimensional, and (c) Markovian approaches.

First, in two-attribute warranty policies, product failures are dependent on the age X and the usage Y of a product. Thus, the sequence of product failures can be modeled as a counting process on the two-dimensional plane of time and mileage. In the counting process, the time and the usage between successive failures can be described as a bivariate **probability density function**. This method of modeling is called a *two-dimensional approach* to a two-attribute warranty plan. As a bivariate probability density function, the bivariate exponential distribution is a natural choice if we assume that the times and the usages between successive failures are independent and identically distributed random variables. The beta-Stacy distribution and the multivariate Pareto distribution of the second kind have been also considered by other researchers [10].

Second, in many practical situations, the failure process on the two-dimensional plane can be represented by a univariate renewal process. This formulation method is referred to as the *one-dimensional approach*, which takes advantage of the linear relationship between X and Y . For most drivers, for example, the average mileage driven per year is constant; that is, the product usage Y is a linear function of the time X .

Note that not all products of a kind have the same usage rate; a high-intensity user like a traveling salesman for example, has a high usage rate, while a low-intensity user like a retired grandmother presumably has a low rate of use. Thus, the usage rate is assumed to be a nonnegative random variable of the continuous type. The distribution of the usage rate could be modeled satisfactorily by a gamma distribution as in Moskowitz and Chun [8]; by changing its parameter values, we can represent a wide variety of distributions with different location, dispersion, shape, and the like. Other types of distributions, such as the uniform distribution, the β -weighted two-point distribution, and the

4 Multiattribute Warranty Policies

exponential distribution, have also been considered in literature.

Third, in most practical situations, the age x^* and the usage y^* in two-attribute warranty policies take discrete values; that is, it is unimaginable to offer a 5.2-year, 71 534-mi protection plan, even though those are the optimal values for a given warranty cost. Thus, two-attribute warranty policies can be modeled *via* a Markovian approach [11], in which the usage rate per year is discretized as a *state* and the time is also discretized as a *transition*. Figure 3 for example, shows a transition probability matrix for a 5-year, 50 000-mi warranty plan.

In the transition probability matrix in Figure 3, the state i is the mileage of an automobile, while the state ∞ represents the automobiles with more than 50 000 mi. The transition probability p_{ij} is the probability that the state of an automobile with the mileage in the range i will be changed to the state j over a period of 1 year. The state ∞ is an *absorbing* state, while other states are *transient*. Thus, two-attribute warranty policies can be easily modeled as an absorbing Markov chain, and we can find many interesting facts about the absorbing chain such as the expected number of times that each state will be entered before we reach an absorbing state. We can also consider the discounting factor per transition and the repair cost for each state.

Concluding Remarks

Warranties have been important elements in business planning and decision making for manufacturers and producers of services. In this note, we have investigated various two-attribute warranty policies and reviewed three different modeling approaches, but no research works have been reported in the

$$P = \begin{matrix} & \begin{matrix} 0-10 & 10-20 & 20-30 & 30-40 & 40-50 & \infty \end{matrix} \\ \begin{matrix} 0-10 \\ 10-20 \\ 20-30 \\ 30-40 \\ 40-50 \\ \infty \end{matrix} & \left\{ \begin{array}{cccccc} 0.1 & 0.2 & 0.3 & 0.3 & 0.1 & 0 \\ 0 & 0.1 & 0.4 & 0.3 & 0.1 & 0.1 \\ 0 & 0 & 0.2 & 0.4 & 0.2 & 0.2 \\ 0 & 0 & 0 & 0.2 & 0.4 & 0.4 \\ 0 & 0 & 0 & 0 & 0.3 & 0.7 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{array} \right\} \end{matrix}$$

Figure 3 An example of the transition probability matrix in the Markovian approach

open literature that compare the effectiveness of those approaches. There may be some cases where the more mathematically onerous two-dimensional method should be used. There may be other cases in which a simpler method, such as the one-dimensional and Markovian approaches, is sufficient enough to model the aggregate behavior of entire products. But our past experience in decision analysis and on other management science problems suggests that the differences among them will be nominal. An empirical study based on automobile warranty data could answer some questions as to which approaches are more effective in modeling the two-dimensional failure process and in estimating the parameters of warranty models.

Since its appearance in literature in the late 1980s, the two-attribute warranty policy has been extended and generalized in many different directions by releasing some of the basic assumptions in original models and proposing other new policies. But few research models have been successfully applied to the automobile industry. The new research direction in the area of two-attribute warranty policy should be not just to propose another decision model that is based on an artificial fact, but to collect empirical data from the industry to address real problems that are empirically grounded – not only the source that came from the field, but also the solution is of interest to the practitioners.

Warranty Modeling

Introduction

A warranty is a commitment by a manufacturer or producer to provide products or services of acceptable quality for some specified period of time. During the warranty period the producer assumes some portion of the expenses from the repair or replacement of products that are defective or fail to meet customer expectations. Warranties have been in existence since people have exchanged goods and services [1], but it has only been during the past 50 years that quantitative methods have evolved for treating warranty decisions in the production of consumer products. Early efforts in warranty modeling focused on accounting for product costs and in establishing market position for manufactured products, but by the 1970s the onset of global competitiveness and needs for productivity improvement led to a major shift to a quality focus in manufacturing. Consequently, interest grew in developing methods for analyzing and evaluating economic decisions pertaining to the development and planning of warranties [2].

This article summarizes quantitative models for examining warranty decisions. Although the methods presented can also be applied to service systems, we will restrict attention to the view of a manufacturer producing consumer products. Most products are covered by some warranty either directly or indirectly through consumer protection laws. Following a list of notation and acronyms, in the next section we discuss the basic types of warranties that are applied to consumer products. We then present models for predicting the warranty costs, the amount of reserve for covering future costs, and determining optimum warranty periods, followed by some concluding remarks.

Notation

- A : fixed cost for administering a warranty program
- b_0, b_1 : parameters for warranty benefit function
- $B(w)$: expected cost–benefit function for warranty over $(0, w)$
- c_0 : initial unit cost for warranty failure
- c_1 : unit repair/replacement cost

- $C(w; \phi)$: expected cost for warranty of length w under policy ϕ
- δ : discounting factor, $0 \leq \delta \leq 1$
- $f(t), F(t)$: probability density, cumulative distribution function
- $F^{(n)}$: n -fold convolution of F with itself
- K : production lot size
- λ : parameter for the exponential distribution
- $M(t), m(t)$: renewal function, renewal density function
- $N(t)$: number of warranty failures in $(0, t)$
- π : expected price change per period
- warranty policy**
- ϕ :
- $R(w)$: reserve resources for warranty of length $w > 0$
- θ : expected rate of return
- $X(t)$: unit **warranty cost**
- $X_D(t)$: unit warranty cost with discounting.

Types of Warranties

A warranty is specified by a period of coverage and a set of conditions for compensation. It can be renewing so that items replaced because of failures during the warranty period are granted new warranties, or it can be nonrenewing whereby the period of coverage is fixed. Renewing warranties generally only apply to irreplaceable items that are relatively inexpensive. Most warranties are based on free replacement or *pro rata* rebate schemes.

Free-Replacement Warranty (FRW)

Under a free-replacement policy, the manufacturer absorbs all costs associated with the repair or replacement of products that fail during the warranty period. The free-replacement warranty (FRW) policy is common for repairable items like televisions, washing machines, and lawn mowers that can be brought back to a good-as-new operating condition through repairs. It also applies to nonreparable items like flashbulbs, disposable medical products, and inexpensive electronic components.

Let T be a random variable representing the time to failure of a product that has a repair or replacement cost to the manufacturer of c_1 dollars per unit. Under the FRW policy, the unit cost to the manufacturer

2 Warranty Modeling

Figure 1 Unit warranty cost for FRW and PRW policies

at time t for a warranty of length $w > 0$, shown in Figure 1(a), is

$$X(t) = \begin{cases} c_1, & 0 < t \leq w \\ 0, & t > w \end{cases} \quad (1)$$

Therefore, the expected cost of a single failure is

$$E[X(t)] = \int_0^w c_1 f(t) dt = c_1 F(w) \quad (2)$$

where $f(t)$ and $F(t)$ are the probability density and cumulative distribution functions for T .

Pro rata Replacement Warranty

A *pro rata* policy provides customers with an amount of rebate that is a function of the age of the item when it fails within the warranty period. This policy is applied to nonrepairable items. Products like tires are generally sold with a *pro rata* replacement warranty (PRW) policy.

Under a PRW policy with a linear *pro rata* function, an item that costs the manufacturer c_0 dollars per unit that is sold with a warranty of length $w > 0$ has a unit cost at time t , as shown in Figure 1(b), that is given by

$$X(t) = \begin{cases} c_0 \left(\frac{w-t}{w} \right), & 0 < t \leq w \\ 0, & t > w \end{cases} \quad (3)$$

The customer must be willing to pay the complement portion of the cost, i.e., $c_0 t/w$, to execute the warranty under a PRW policy. The expected unit cost is

$$E[X(t)] = \int_0^w c_0 \left(\frac{w-t}{w} \right) f(t) dt \quad (4)$$

or

$$E[X(t)] = c_0 F(w) - \frac{c_0}{w} \int_0^w t f(t) dt \quad (5)$$

Example 1 A turbine engine with a manufacturer's cost of \$1000 is sold under a 15 000-h PRW policy. The failure rate for the engine is 2×10^{-5} failures per h of operation. Assume the lifetime of the engine is exponentially distributed. Find the expected unit warranty cost.

Solution Substituting into equation (5) for the exponential distribution

$$\begin{aligned} E[X(w)] &= c_0[1 - e^{-\lambda w}] + \frac{c_0}{w} \int_0^w t \lambda e^{-\lambda t} dt \\ &= c_0(1 - e^{-\lambda w}) + \frac{c_0}{\lambda w} [1 - (1 + \lambda w)e^{-\lambda w}] \end{aligned} \quad (6)$$

For the case where $c_0 = \$1000$; $w = 15\,000$ h; and $\lambda = 2 \times 10^{-5}$ failures per h,

$$\begin{aligned} E[X(15\,000)] &= 1000[1 - e^{-(2 \times 10^{-5})(15\,000)}] \\ &\quad + \frac{1000}{(2 \times 10^{-5})(15\,000)} \\ &\quad \times \left\{ 1 - [1 + (2 \times 10^{-5})(15\,000)] \right. \\ &\quad \left. \times e^{-(2 \times 10^{-5})(15\,000)} \right\} = \$382.30 \quad (7) \end{aligned}$$

Combined FRW/PRW

Many products are sold under a combined policy whereby items that fail during an initial period $(0, w_1)$ are covered in full by an FRW policy, followed by a PRW policy during (w_1, w_2) . Let c_0 be the initial cost. The unit cost, as shown in Figure 2,

Figure 2 Unit warranty cost for combined FRW/PRW policy

is given by

$$X(t) = \begin{cases} c_0, & 0 < t \leq w_1 \\ c_0 \left(\frac{w_2 - t}{w_2 - w_1} \right), & w_1 < t \leq w_2 \\ 0, & t > w_2 \end{cases} \quad (8)$$

The expected cost for a single claim, i.e., single failure, is therefore,

$$\begin{aligned} E[X(t)] &= c_0 \int_0^{w_1} f(t) dt + \frac{c_0}{w_2 - w_1} \\ &\quad \times \int_{w_1}^{w_2} (w_2 - t) f(t) dt \\ &= c_0 F(w_1) + \left(\frac{c_0 w_2}{w_2 - w_1} \right) [F(w_2) - F(w_1)] \\ &\quad - \frac{c_0}{w_2 - w_1} \int_{w_1}^{w_2} t f(t) dt \end{aligned} \quad (9)$$

Integrating the last term by parts and simplifying,

$$E[X(t)] = \left(\frac{c_0}{w_2 - w_1} \right) \int_{w_1}^{w_2} F(t) dt \quad (10)$$

Example 2 A tire manufacturer produces a particular brand of tire at a cost of \$50 per tire that is sold under a 24-month warranty with a 90-day FRW policy followed by a PRW policy for the remaining period. Failure times are exponentially distributed with a mean time to failure of 30 months. Assume customers are willing to pay their prorated portion of replacement costs when it is required.

Here we have the parameter values as follows:

$$\begin{aligned} c_0 &= \$50, w_1 = 3 \text{ months}, \\ w_2 &= 24 \text{ months}, \lambda = 1/30 \end{aligned}$$

Substituting into equation (10), the expected unit cost is

$$\begin{aligned} E[X(24)] &= \left(\frac{50}{24 - 3} \right) \int_3^{24} (1 - e^{-t/30}) dt \\ &= 2.38[21 + 30(e^{-24/30} - e^{-3/30})] \\ &= \$17.46 \end{aligned} \quad (11)$$

Expected Discounted Unit Cost

For cases where warranty repair and replacement costs are high and warranties are of relatively long

duration, cost models should include consideration for the time value of money. Denoting the discount factor by δ , $0 < \delta < 1$, the expected discounted unit cost is

$$E[X_D(t)] = E[e^{-\delta t} X(t)] \quad (12)$$

FRW with Discounting. From equation (2) it follows that

$$E[X_D(t)] = c_1 \int_0^w e^{-\delta t} f(t) dt \quad (13)$$

For failure time distributed exponentially,

$$E[X_D(t)] = c_1 \int_0^w \lambda e^{-(\lambda+\delta)t} dt \quad (14)$$

or

$$E[X_D(t)] = \frac{\lambda c_1}{\lambda + \delta} [1 - e^{-(\lambda+\delta)w}], \quad w \geq 0 \quad (15)$$

PRW with Discounting. Modifying equation (5) for discounting,

$$\begin{aligned} E[X_D(t)] &= c_1 \int_0^w e^{-\delta t} \left(\frac{w - t}{w} \right) f(t) dt \\ &= c_1 \int_0^w e^{-\delta t} f(t) dt - \frac{c_1}{w} \int_0^w e^{-\delta t} t f(t) dt \end{aligned} \quad (16)$$

and integrating by parts it is easily shown that

$$E[X_D(t)] = \frac{c_1}{w} \int_0^w \int_0^t e^{-\delta \tau} f(\tau) d\tau \quad (17)$$

For exponentially distributed warranty failures,

$$\begin{aligned} E[X_D(t)] &= \frac{c_1}{w} \int_0^w \int_0^t \lambda e^{-(\lambda+\delta)\tau} d\tau \\ &= \frac{c_1}{w} \int_0^w \frac{\lambda(1 - e^{-(\lambda+\delta)\tau})}{\lambda + \delta} d\tau \end{aligned} \quad (18)$$

which can be simplified to

$$\begin{aligned} E[X_D(t)] &= \frac{\lambda c_1}{\lambda + \delta} - \frac{\lambda c_1}{w(\lambda + \delta)^2} \\ &\quad \times [1 - e^{-(\lambda+\delta)w}], \quad w \geq 0 \end{aligned} \quad (19)$$

Example 3 A special device costs the manufacturer \$2500 to produce and is sold under a 5-year PRW policy. Failure times are exponentially distributed

4 Warranty Modeling

with a mean time to failure of 4 years. Given that the value of money is discounted at a rate of 6%, determine the expected cost for warranty failures. Assume that customers are willing to pay their share of costs when warranty failures occur.

Substituting the parameter values $\lambda = 1/4$, $c_1 = \$2500$, and $\delta = 0.06$ into equation (19),

$$E[X_D(t)] = \frac{(0.25)(2500)}{0.25 + 0.06} - \frac{(0.25)(2500)}{5(0.25 + 0.06)^2} \times [1 - e^{-(0.25+0.06)5}] = \$991.48 \quad (20)$$

Warranty Cost Models

Warranty decisions can be critical in product planning, particularly for new product development. The manufacturer needs to know enough about the failure characteristics and related costs to predict the overall product cost. There is risk in the revenues from sales and of course the warranty costs. The manufacturer's total cost is the initial cost of producing the product plus the accumulation of costs for **warranty claims** from failures that occur during the warranty period. The following models are useful in examining the costs for given warranty policies, estimating the amount of reserve to cover warranty costs, and determining minimum cost warranties.

Predicting Manufacturer Cost

Consider a product with initial production cost c_0 that is sold under a warranty policy ϕ , such as FRW, PRW, or some other policy. We shall assume that the times between warranty failures occur as independent random variables $F(t)$ that are identically distributed and each such event $i = 1, 2, \dots$ results in a cost $X_i(t)$. The manufacturer's expected cost is then given by

$$C(w; \phi) = c_0 + E\left(\sum_{i=1}^{N(w)} X_i(t)\right) \quad (21)$$

From renewal theory (*see* for example [3] and **Renewal Theory**) it follows that with $N(w)$ being a stopping time

$$E\left(\sum_{i=1}^{N(w)} X_i(t)\right) = E[X_i(t)]E[N(w)] \quad (22)$$

where $E[X_i(t)]$ is the expected unit cost for a warranty failure given by equations (2) and (5) for FRW and PRW policies. Further, with $X_i(t)$ properly behaved over time $t > 0$, $E[X_i(t)]$ can be treated as a constant c_1 then from equation (19)

$$C(w; \phi) = c_0 + c_1 M(w) \quad (23)$$

where

$$M(w) = E[N(w)] = \sum_{n=1}^{\infty} F^{(n)}(t) \quad (24)$$

is the renewal function and $F^{(n)}(t)$ is the n -fold convolution of $F(t)$ with itself (*see* **Renewal Theory**).

Fixed-Period Warranties. For most consumer products warranty coverage expires after some fixed period of time $w > 0$. Under ideal conditions an item is placed in service functioning during its useful life whereby the failure times are exponentially distributed with

$$F(t) = 1 - e^{-\lambda t}, \quad \lambda > 0, \quad t \geq 0 \quad (25)$$

Therefore the counting distribution for the number of failures in $(0, t)$ is Poisson distributed with rate $\lambda > 0$ and hence $M(w) = \lambda w$ and in equation (22)

$$C(w; \phi) = c_0 + c_1 \lambda w \quad (26)$$

For non-Poisson failures, which are more typical, it will be necessary to compute $M(w)$.

Example 4 An item is produced at a cost of \$100 and sold with a complete warranty under an FRW policy for w months during which the average unit repair cost to the manufacturer is \$30. The **probability density function** for the time between warranty failures is

$$f(t) = \frac{16}{9} t e^{-\frac{4}{3}t}, \quad t \geq 0 \quad (27)$$

which is the Erlang probability density function. It can be shown (e.g., see [4, Appendix C]) that

$$M(t) = \frac{2}{3}t - \frac{1}{4} + \frac{1}{4}e^{-\frac{4}{3}t}, \quad t \geq 0 \quad (28)$$

Substituting the costs $c_0 = 100$ and $c_1 = 30$, and $M(w)$ from equation (28), the expected cost from

equation (23) is given by

$$C(w; FRW) = \frac{185}{2} + 20w + \frac{15}{2}e^{-\frac{4}{3}w}, \quad w \geq 0 \quad (29)$$

Computations of $M(w)$ often require numerical methods for solution. For cases where failure rates are relatively small (i.e., $P(N(w) > 1) \approx 0$), $M(t)$ can be approximated by $F(t)$.

Renewing Warranties. For the case of a renewing warranty, the length of the warranty period is random, since it renews itself to an additional warranty of length w each time a failure occurs at a time $t < w$. So the warranty period is sum of independent random variables. Denoting the time to warranty i by T_i , $i = 1, 2, \dots$, the time to a failure n is then, $S_n = T_1 + T_2 + \dots + T_n$. It follows that for the number of failures in $(0, w)$, $N(w) = n$, then $S_{n+1} > w$. Therefore,

$$P[N(w) = 0] = P[S_1 > w] = 1 - F(w) \quad (30)$$

and

$$\begin{aligned} P[N(w) = 1] &= P[S_2 > w] \\ &= P[T_1 < w]P[T_2 > w] \\ &= [1 - F(w)]F(w) \end{aligned} \quad (31)$$

and further by induction,

$$\begin{aligned} P(N(w) = n) \\ = [1 - F(w)][F(w)]^{n-1}, \quad n = 1, 2, \dots \end{aligned} \quad (32)$$

which is the geometric distribution with mean given by

$$E[N(w)] = \frac{1}{1 - F(w)} \quad (33)$$

It therefore follows from equation (23) that

$$C(w; \phi) = c_0 + \frac{E[X_1(w)]}{1 - F(w)} \quad (34)$$

and since in general for items under renewing warranty $c_1 = c_0$, for an FRW policy from equation (2) the total expected cost is given by

$$C(w; FRW) = \frac{c_0}{1 - F(w)} \quad (35)$$

For the PRW policy with renewing warranty, from equations (5) and (22),

$$C(w; PRW) = \frac{c_0 + \frac{c_0}{w} \int_0^w t f(t) dt}{1 - F(w)} \quad (36)$$

Example 5 Suppose that the turbine engine of Example 1 is under a renewing PRW policy. With $c_0 = \$1000$; $w = 15\,000$ h; and $\lambda = 2 \times 10^{-5}$ failures per h; substituting into equation (36)

$$\begin{aligned} C(15\,000; PRW) \\ = \frac{1000 + \frac{1000}{15\,000} \int_0^{15\,000} (2 \times 10^{-5}) t e^{(-2 \times 10^{-5})t} dt}{e^{(-2 \times 10^{-5})w}} \\ = \$1516 \end{aligned} \quad (37)$$

For the comparable fixed warranty the unit cost of failure is \$382.30 from Example 1, and substituting this value into equation (26) we have for the total cost,

$$\begin{aligned} C(w; PRW) &= 1000 + (383.30)(2 \times 10^{-5})(15\,000) \\ &= \$1,115 \end{aligned} \quad (38)$$

which, as expected, is much less cost to the manufacturer. Obviously, renewing warranties are normally not used for products with costs and failure characteristics like these.

Determining Warranty Reserve

Warranty reserve is the amount of money the manufacturer should set aside to cover forthcoming costs for warranty expenses. Proper warranty reserve management can be critical since too much reserve can result in lost opportunity for investing in other sources of revenue generation, and under **estimation** can result in a false profit plan. The following method first proposed by Menke [5] and later generalized by others [6, 7] is based on predicting reserve as a fraction of the total sales of a product.

Consider a product that is produced and sold in a lot of size K units at price c_1 dollars per unit under a PRW policy over the period $(0, w)$. The failure time probability density function $g(t)$, $t \geq 0$, is presumed to be known. The unit warranty cost from

6 Warranty Modeling

equation (5) is

$$X(t) = \begin{cases} c_0 \left(\frac{w-t}{w} \right), & 0 < t \leq w \\ 0, & t > w \end{cases} \quad (39)$$

Denoting the rate of return and expected price change per period by θ and π respectively, the future amount of reserve is given by

$$d(R) = X(t)d(K \cdot G(t)) \quad (40)$$

or

$$d(R) = c_1 \left(1 - \frac{t}{w} \right) (1 + \theta)^{-t} (1 + \pi)^{-t} \quad (41)$$

For $0 < \theta < 1$ and $0 < \pi < 1$,

$$(1 + \theta)^{-t} (1 + \pi)^{-t} \simeq (1 + \theta + \pi)^{-t} = b^{-t} \quad (42)$$

and it follows that

$$R(w) = \left(\frac{Kc_1}{w} \right) \int_0^w (w-t)b^{-t}g(t)dt \quad (43)$$

Example 6 Consider an example from [4] where an item sold under a 1-year PRW policy has failure times that are exponentially distributed at a rate of 0.4 failures per year. Interest is 5% per period and price changes at a rate of 4% per period.

Substituting the exponential probability density function into equation (43)

$$\begin{aligned} R(w) &= \left(\frac{Kc_1}{w} \right) \int_0^w (w-t)b^{-t}\lambda e^{-\lambda t} dt \\ &= Kc_1 \int_0^w e^{-t(\ln b + \lambda)} dt \\ &\quad - \left(\frac{Kc_1\lambda}{w} \right) \int_0^w te^{-t(\ln b + \lambda)} dt \end{aligned} \quad (44)$$

On simplifying these two terms it can be shown that

$$R(w) = \frac{Kc_1\lambda}{\ln b + \lambda} \left[1 - \frac{1 - b^{-w}e^{-\lambda w}}{w(\ln b + \lambda)} \right] \quad (45)$$

For $\lambda = 0.4$ failures per year, $w = 1$ year, $\theta = 0.05$, $\pi = 0.04$, and hence $b = 1.09$,

$$\begin{aligned} R(1) &= \frac{Kc_1(0.4)}{\ln(1.09) + 0.4} \left[1 - \frac{1 - (1.09)^{-1}e^{-0.4(1)}}{1(\ln(1.09) + 0.4)} \right] \\ &= 0.3669Kc_1 \end{aligned} \quad (46)$$

therefore $R(1)/Kc_1 = 0.3669$. This indicates that for each item sold, 37% of the unit cost should be set aside to cover warranty costs.

Optimum Warranty Policies

The determination of optimum warranty coverage requires knowledge of the product failure characteristics, the cost for repairs and replacements, and some measure of the benefit to the manufacturer for providing the warranty. Warranty benefit is indeed difficult to quantify but there are indirect means of capturing relative effects through marketing, consumer surveys, and other studies that can be used to estimate benefit. Here we will appeal to the argument that benefit will vary in a decreasing manner with the cost of marketing and advertising [8].

Denoting the expected benefit by $B(w)$, and the expected cost by $C(w)$, $w \geq 0$ the expected total cost is given by

$$T(w) = A + B(w) + C(w) \quad (47)$$

where A is the fixed administrative costs for the warranty program. $C(w)$ is an increasing function of w , whereas $B(w)$ will decrease with increasing warranty intervals. We assume that $B(w)$ and $C(w)$ are monotonic and $T(w)$ is convex. Suppose we consider an FRW policy with quadratic benefit given by

$$B(w) = (b_0 - b_1w)^2, \quad 0 \leq b_0/b_1 \leq w \quad (48)$$

The total expected cost is then given by

$$\begin{aligned} T(w) &= (A + c_0) + c_1M(w) + (b_0 - b_1w)^2, \\ 0 &\leq b_0/b_1 \leq w \end{aligned} \quad (49)$$

To find the optimum value of w ,

$$\frac{d}{dw}T(w) = c_1m(w) + 2(b_0 - b_1w)(-b_1) \quad (50)$$

where $m(w) = d/dwM(w)$ is the renewal density function and it follows that the optimum choice of warranty length w^* will satisfy the equation

$$c_1m(w) + 2b_1^2w - 2b_0b_1 = 0 \quad (51)$$

For the case of exponentially distributed failure times, the number of failures in $(0, w)$ is Poisson distributed

and $M(w) = \lambda w$, thus from equation (51) we have the optimum warranty interval given by

$$w^* = \frac{2b_0b_1 - c_1\lambda}{2b_1^2} \quad (52)$$

Example 7 A nonreparable item costs the manufacturer \$500 and failure times are distributed exponential with a rate of 0.75 failures per year. Without a warranty it is estimated that the manufacturer will have to incur a cost of \$22 500 to market the item, and with warranty the cost would decline as $(150 - 15w)^2$. So $c_1 = 500$, $\lambda = 0.75$, $b_0 = 150$, and $b_1 = 15$, and in equation (52)

$$w^* = \frac{2(150)(15) - 500(0.75)}{2(15)^2} = 9.2 \text{ years} \quad (53)$$

Concluding Remarks

The models presented in this paper are useful in predicting costs and addressing warranty economic trade-offs for developing policies. The FRW and PRW policies considered are fundamental and the most common policies that are applied to consumer products. Details on other warranty policies can be found in [9] and [10], and for an extensive review of economic issues pertaining to warranty analysis and planning decisions see [2] and [11].

The development of quantitative methods for warranty decisions has evolved through predicting and accounting for the costs for examining marketing strategies, developing and analyzing warranty policies, and most recently methods for integrating warranty feedback information for quality improvement. The modern view of quality is much broader now that the customer base is much more informed and critical of the value of their purchases. Quality is determined by a set of several elements that characterize the way a product is designed, developed, produced, and accepted by its users. Included among these elements will be some measure of performance capability, conformance quality of how well the design and manufacturing standards are achieved, product life, and other measures that pertain to customer acceptance. Since the cost and frequency of warranty claims are affected by all of these elements of quality, warranty performance provides an indirect measure for tracking the relative quality of products. More

details on using warranty information feedback and to develop quality improvement strategies can be found in [4].

Inspection Policies for Reliability

Introduction

Regular inspections can reduce the risk of equipment failure and so increase reliability. We may think of industrial plants, production lines, pipelines and other infrastructure such as buildings and roads, or merely of the annual inspection of domestic gas boilers, or the regular servicing of our cars. In healthcare, dental inspections and breast cancer screening (*see **Early Detection Programs in Medical Care***) reduce the risk of painful or life-threatening outcomes.

In every field, there are detailed engineering-based requirements of what inspections should look for, and how they should be carried out. Reliability-centered maintenance gives a general strategy. This article is concerned rather with inspection *policy*. When inspections are performed periodically, we ask how often they should be performed. Infrequent inspection does not prevent expensive failures, while too frequent inspection is costly, and may require extensive **system downtime**. We hope to find the golden mean.

All inspection models necessarily include parameters, and one can find the optimum policy to guarantee a specified reliability or to minimize cost per unit time as a function of the parameter values. Without **estimation** of these values, the modeling is useless. Operational researchers often content themselves with deriving an optimal policy given a model with known parameter values. This ignores two crucial steps necessary for practical use of the model: checking that the model is appropriate, and estimating its parameter values. One should also carry out a sensitivity analysis.

Two extreme cases for modeling may be distinguished. Equipment such as a production line is in use all the time, while standby equipment such as an alarm system, a fire extinguisher, an electrical relay, a life vest or an airbag “waits to work”. The item may have failed and be nonfunctional. Inspection reveals that the item is in a failed state. The simplest policy is to replace failed items, although it could be that a “minimal repair” would be carried out, to restore the item to a working state that is not however “good as new”.

When the system is in constant use, clearly an inspection cannot simply reveal that it is in a failed state—it was still functioning when shut down for inspection. The modeling of the benefit of an inspection must be more subtle. The inspection can reveal that the equipment is at risk of failure soon, that is, before the next scheduled inspection. Maybe the pipeline has worn dangerously thin in spots, the motorway bridge is cracked, or a tooth is decaying. Remedial action must be taken to prevent failure. Some components of a system may be known to need regular replacement, in which case the inspection is also an overhaul, as in replacing the oil and the air filters in a car. There are also intermediate cases, for example a 2-component system where one is in “warm standby”, and the system fails if both components fail.

Some mathematical models of inspection are essentially “wear models” (*see **Damage Processes***), that model the thickness of a pipeline or the growth of a crack. If we can specify an acceptable minimum reliability, or assign a cost to failure, we can find the total cost of inspections plus unscheduled failures, and so find the optimum policy, for example “inspect every x years and replace pipe segments with spots less than y -mm thick”. These models are naturally application-specific. Baker [1] gives this type of model for breast cancer screening. The processes of tumor origination and growth are modeled, and the probability of tumor detection at screening as a function of tumor size. Finally, presentation with cancer and subsequent survival are modeled as a function of tumor size. Dynamic programming is used to find the optimal screening ages, with life-years as the criterion to be maximized (*see **Dynamic Programming Methods in Repair and Replacement***).

In contrast, a class of models that can be applied to a wide variety of situations is Christer’s delay-time model. Defects arise randomly (in a Poisson process, *see **Poisson Processes***) and lead to failure after a random time, the delay time. This is the sojourn time in the defective state, and the probability distribution of sojourn time need not be exponential. The function of inspection is to detect and eliminate defects before they cause failure. Figure 1 illustrates this. This is an attractively simple model, because the condition of an item is either OK or defective, and exactly what constitutes a defect is left as an operational decision for maintenance engineers.

2 Inspection Policies for Reliability

Figure 1 How inspections prevent failures for the delay-time model. The horizontal axis represents time and the open circles represent the origination of defects, the closed circles represent failures and the vertical lines inspections. With periodic inspections, as in (b) of the figure, the second, fourth, fifth and eighth defects have now been detected and repaired, and so have not caused failures

Thomas *et al.* [2] give a taxonomy of inspection models. It is not of course possible to give an exhaustive account of inspection models here, but the following sections give simple examples of policies for standby and continuous operation systems, together with some useful references.

Standby Systems

The simplest scenario is that we wish to increase reliability by replacing failed items such as life vests at regular intervals T . We assume that inspection and replacement take negligible time. For $nT < t < (n+1)T$ the availability (*see System Availability*) $A(t)$ is given by

$$A(t) = \sum_{i=0}^n p_i S(t - iT) \quad (1)$$

where $S(t)$ is the survival function of the failure time distribution of the item, p_i is the probability that the item was replaced at time iT , and $p_0 = 1$. Since $A\{(n+1)T\} = 1 - p_{n+1}$, equation (1) gives the recursive scheme

$$p_{n+1} = 1 - \sum_{i=0}^n p_i S(t - iT) \quad (2)$$

for the calculation of the replacement probabilities.

Figure 2 shows the availability of an item under such a scheme. The process soon settles down to its asymptotic state, where the p_i are constant, so that $p_i \rightarrow p$. Equations (1) and (2) then yield

$$p = \frac{1}{\sum_{i=0}^{\infty} S(iT)}$$

$$A(nT + u) \longrightarrow \frac{\sum_{i=0}^{\infty} S(u + iT)}{\sum_{i=0}^{\infty} S(iT)} \quad (3)$$

where $0 \leq u < T$. For an exponential distribution of failure time, with mean μ , $A(nT + u) = \exp(-u/\mu)$ for all n .

The availability decreases from 1 just after an inspection to $1 - 1/\sum_{i=0}^{\infty} S(iT)$ just before the next.

Choice of a suitable inspection interval would proceed by graphing $A(t)$ as in Figure 2 for various inspection intervals, and choosing one for which minimum availability and inspection cost was acceptable. There is likely to be little data available on item lifetime, but after some experience Weibull parameters could be estimated by a maximum likelihood fit to replacement data. The maximum likelihood method can cope with the interval censoring arising from our knowing only that the item failed during some period T , and the censoring arising from some items not having failed at all when the data came to hand. For example, if m_i items were regularly inspected and found functioning after $i - 1$ periods but failed after i periods, and $n_i - m_i$ items had not failed after their latest inspection at the i th period, the

Figure 2 Availability for a standby system with inspection period $T = 1/4$ and replacement of failed items, where the failure time follows a Weibull distribution with survival function $S(t) = \exp(-t^2)$

likelihood function to be maximized for the Weibull parameters would be

$$\mathcal{L} = \prod_{i=1}^{\infty} \{S((i-1)T) - S(iT)\}^{m_i} S(iT)^{n_i - m_i} \quad (4)$$

When costs can be assigned, let c_1 be the cost of inspection, c_2 the cost of replacement, and c_3 the cost of nonavailability of the item per unit time. Then the mean cost C per unit time is given by

$$C(T) = \frac{c_1 + c_2 p + c_3 \int_0^T (1 - A(nT + u)) du}{T}$$

which reduces to

$$C = \frac{c_1 + \frac{c_2 - c_3 \mu}{\sum_{i=0}^{\infty} S(iT)}}{T} + c_3 \quad (5)$$

The optimum period T is found by minimizing $C(T)$. From equation (5), a necessary condition for inspections to be worthwhile is that $c_3 \mu > c_2$, so that the expected gain from operating the item exceeds its cost.

A comprehensive reference to the nonstatistical aspects of inspection models for standby systems is Chapter 8 of [3], where an inspection policy for a standby electric generator is derived, when repair time is not negligible. The earliest work is by [4], who derived inspection times T_i to minimize the total cost of checking and replacing a unit, plus the cost of undetected failure, taken as proportional to the “down” time, over the life of the unit. Another important early reference is [5].

The T_i can also be chosen to minimize cost per unit time if the unit is replaced on failure over an infinite time horizon.

There are very many modeling variations; for example, inspection may be imperfect and detect a failed item with some probability $q < 1$, the item may be minimally repaired rather than replaced, and so on (see **Imperfect Repair**).

Continuous Operation Systems

This example of the use of the delay-time model is based upon [6], an early and influential case study for a high-speed canning line. It is further discussed in [7].

Inspection was carried out every $T = 24$ hours. In general, inspection was found to result on average in a downtime of $65.5/24 = 2.73$ hours per week. Assuming that the inspection downtime period is independent of inspection frequency, downtime due to inspection is $65.5/T$ per week. The mean number of defects appearing per week was measured as 16.6, and the fraction $b(T)$ of them which resulted in failures caused an average downtime of 0.698 h, so that the downtime per week due to failures was modeled as $11.59b(T)$. The downtime per week as a function of T was therefore

$$\frac{65.5}{T} + 11.59b(T)$$

This formula is approximate, and uses the fact that in this case manpower for inspection was not a problem: flexible manpower at inspection meant that an inspection and repair took the same time however many defects had to be fixed. To optimize T , we need to know b as a function of T .

Assuming a stationary process, a defect arising in the interval $(0, T)$ is assumed to arrive at time u from the last inspection with **pdf**. $g(u) = 1/T$. The probability that a random defect causes a failure before it is caught at the next inspection is

$$\begin{aligned} b(T) &= \int_0^T g(u) F(T - u) du \\ &= (1/T) \int_0^T (1 - \exp\{-\eta u\}) du \end{aligned} \quad (6)$$

assuming an exponential distribution for the delay time, when the distribution function $F(h) = 1 - \exp(-\eta h)$. Hence

$$b(T) = 1 - (1 - \exp\{-\eta T\})/\eta T \quad (7)$$

this is the required formula for $b(T)$.

The observed value of b was 0.396, for the current practice with $T = 24$ hours. Solving equation (7) gives $\eta = 0.0463$, which provides a delay-time distribution estimate that is tuned to current practice.

Figure 3 shows estimated downtime per week as a function of T , and it can be seen that daily inspection is about optimal.

There has been quite an industry in developing the delay-time model from this simple beginning. The concept of a two-stage failure process also arose at about the same time in the context of cancer

Figure 3 Downtime per week against the interval between inspections for a case study of a canning line from [6]

screening [8]. In Operational Research, Christer's delay-time model was then developed by extending it to individual components [9], making the model more complex (e.g., consideration of fault injection at maintenance [10]), and estimating parameters by maximum likelihood rather than by the method of moments [11, 12].

The estimation of model parameters is a major problem. In this simple example, the method of moments was used to equate observed variables to model predictions. Estimation requires some subtlety if the only data available is the historical record of failures and results found at inspection under some existing inspection policy that we hope to optimize. Likelihood-based statistical estimation can usually cope with problems of censoring that may arise, and some method of choosing the best model such as minimum Akaike information criterion (AIC) is needed. Moving to longer intervals between inspections sometimes requires extrapolation of the tail behavior of fitted distribution functions. For example, the delay-time distribution of a defect can never be known at times larger than the interval between inspections. We rely on the smoothness of the distribution function to extrapolate into the tail.

Experience was gained with a wide variety of applications, for example, building maintenance [13], civil engineering structures [14], industrial plant [15–17], gearboxes [18], pumps [19], concrete structures [20] and much else. Difficulties in obtaining adequate data for making good model predictions led to interest in more efficient statistical inference (e.g. [21]), and also to the elicitation of subjective data (see **Expert Opinion in Reliability**) [17, 22, 23].

Bayesian methods are nowadays increasingly being used by statisticians, and where there is insufficient “objective” data, it can be eked out with subjective data gleaned from maintenance engineers. A Bayesian approach to this model in the context of cancer screening is given in [24]. Reviews of delay-time modeling are found in [21, 25, 26].

Total Time on Test Plots

Introduction

Suppose that we have a complete ordered sample $0 = t(0) \leq t(1) \leq \dots \leq t(n)$ of times to failure from n identical and independent nonrepairable units with life distribution $F(t)$ and survival function $R(t) = 1 - F(t)$. The *TTT* (total time on test) *plot* of these observations is then obtained in the following way

- Let $S_0 = 0$ and calculate the TTT values S_j as
- $S_j = S_{j-1} + (n - j + 1)(t(j) - t(j - 1))$ for $j = 1, 2, \dots, n$.
- Normalize these TTT values by calculating $u_j = S_j/S_n$ for $j = 0, 1, \dots, n$.
- Plot $(j/n, u_j)$ for $j = 0, 1, \dots, n$.
- Join the plotted points by line segments.

Accordingly, the TTT plot consists of line segments starting in the lower left corner and ending in the upper right corner of the unit square. When the sample size n increases to infinity the TTT plot converges to the *scaled TTT transform* of the life distribution $F(t)$ from which the sample has come

Figure 1 TTT plots based on simulated data from a Weibull distribution with $\beta = 2.0$, $n = 10$ in (1) and $\beta = 2.0$, $n = 100$ in (2) and the scaled TTT transform of a Weibull distribution with shape parameter $\beta = 2.0$ in (3). (From Bergman and Klefsjö [2])

[1]. An illustration of different TTT plots and the convergence is found in Figure 1. The scaled TTT transform, defined as

$$\varphi(u) = \frac{1}{\mu} \int_0^{F^{-1}(u)} R(t) dt \text{ for } 0 \leq u \leq 1 \quad (1)$$

where μ is the mean, is, as the name indicates, independent of scale. For instance, for a Weibull distribution with survival function $R(t) = \exp(-(t/\theta)^\beta)$, $t \geq 0$, the transform depends only on β and is independent of the value of θ . Furthermore, every exponential distribution $F(t) = 1 - \exp(-\lambda t)$, $t \geq 0$, is transformed to the diagonal in the unit square, independently of the value of λ ; see curve (3) in Figure 2. Accordingly, different deviations from the diagonal in the unit square of the scaled TTT transform of a life distribution $F(t)$ can be interpreted as different deviations of $F(t)$ from the exponential distribution.

The TTT plot and the scaled TTT transform were introduced by Barlow and Campo [1] primarily for model identification purposes. By comparing the TTT plot based on the obtained times to failure

Figure 2 Scaled TTT transforms from five different life distributions: (1) normal with $\mu = 1$, $\sigma = 0.3$; (2) gamma with shape parameter 2.0; (3) exponential distribution; (4) lognormal with $\mu = 0$, $\sigma = 1$; (5) Pareto distribution with survival function $R(t) = (1 + t)^{-2}$, $t \geq 0$ [© John Wiley & Sons Ltd, New York.]

2 Total Time on Test Plots

with different scaled TTT transforms it is possible to choose a suitable life distribution model. Since then several other applications and generalisations of TTT plotting have appeared, both theoretical and practical. The aim of this presentation is to give an overview of a number of these practical and theoretical applications and support the reader with suitable references for further information.

TTT Plotting for Aging Classification

Different aging properties of $F(t)$ can be translated to properties of the scaled TTT transform of $F(t)$; see Barlow and Campo [1], Barlow [4], Bergman [5], Klefsjö [6]. This gives a source of subjective criteria of different aging properties; see Figure 3. As one important example, a life distribution has *Increasing Failure Rate (IFR)* exactly when the scaled TTT transform is concave [1]. If a unit has IFR “the proneness” to fail increases with the age, which means that there is a certain age at which the unit should be replaced with a new one to minimize the “long-run costs”, e.g., measured as the average long-run cost per unit time. To estimate the optimal replacement age according to this criteria the TTT

Figure 3 Since $F(t)$ has increasing failure rate (IFR) exactly when the scaled TTT transform $\varphi(u)$ is concave we expect a TTT plot based on failure times from an IFR life distribution to behave concavely. This is illustrated here by a TTT plot based on 22 failure times from a tractor engine [© John Wiley & Sons Ltd, WileyInterscience.]

Figure 4 Illustration of estimation of the optimal replacement age based on the TTT plot when the replacement cost is c at age T and K at failure. The failure time $t(j^*)$ corresponding to the touching point at the TTT plot of the line through $(-c/K, 0)$ with the largest slope, is the estimator [© John Wiley & Sons Ltd, New York.]

plot is useful as well [3, 7, 8]; for an illustration see Figure 4.

More discussions related to the correspondence between TTT transforms and aging properties can be found in e.g., Klefsjö [6] and Bergman [5]. Illustrations of how to use the TTT plot and the scaled TTT transform for optimisation related to the age replacement problem with discounted costs are presented by Bergman and Klefsjö [9] and Dohi *et al.* [10], related to **burn-in** problems by Bergman and Klefsjö [11] and when discussing replacements to extend system life by Bergman and Klefsjö [12]. Some interesting papers dealing with problems from practice are Kumar *et al.* [13], Kumar and Westberg [14], Bergman and Klefsjö [15] and Al-Najjar [16].

TTT Plotting When Analyzing Data from Repairable Systems

Suppose that we are studying a single repairable unit. The data normally provided consists of epochs of failure events, measured on an operation timescale or a calendar timescale. In some cases the duration of repair is reported as well. However, in this paper repair times are excluded from the discussion. The sequence of event epochs, i.e., the times to failures, $T_1, T_2, \dots$ give rise to a sequence of interevent times, or interfailure times, $t_j = T_j - T_{j-1}$, also called *local times*. This means that the time to the j th failure T_j is equal to $T_j = t_1 + t_2 + \dots + t_j$.

When studying repairable units, the failure intensity at time T , which intuitively is a measure of the probability that a failure will occur during the next units of time, is of great interest [17]. The intensity of the failure process can be a function of both the running time T , also called *global time*, and the local time t .

When the intensity of the failure process is a function of the running time T only, the failures may occur according to a nonhomogeneous **Poisson process**. This situation is obtained if, for instance, we use a **minimal repair** policy, which means that the unit is repaired to the same state as it had just before the failure occurred. In this situation, the usual assumption of a renewal process to model such data is most often incorrect. For an excellent discussion on analysis of failure data from **repairable systems** and the abuse of the renewal process assumption, see Ascher and Feingold [17].

One of the most popular nonhomogeneous Poisson process models is the one where the **intensity function** $\rho(T)$ is a power of T , i.e., it can be written in the form

$$\rho(T) = \frac{\beta}{\theta} \left(\frac{T}{\theta} \right)^{\beta-1} \quad (2)$$

with constants $\theta > 0$ and $\beta > 0$. This model has been discussed under several different names, many of them including “Weibull” in the name, since the intensity function above has the same form as the failure rate of a Weibull life distribution. However, including “Weibull” in the name of the process has caused a lot of confusion. It gives the incorrect impression that the times between failures follow a Weibull distribution (for a discussion, see [18]). Therefore, we prefer to use the name *power law process*. For an excellent discussion of the power law process, see Rigdon and Basu [19, 20].

Suppose we observe a power law process, with intensity function $\rho(T) = (\beta/\theta)(T/\theta)^{\beta-1}$, until n events have occurred. Suppose further that the events occurred at $T_1, T_2, \dots, T_n$. Møller [21] has shown that if $w_j = -\ln(T_{n-j}/T_n)$, then $w_1, w_2, \dots, w_{n-1}$ is distributed as an ordered sample of size $n-1$ from an exponential distribution with mean $1/\beta$, i.e., from the distribution $F(t) = 1 - \exp(-\beta t)$, $t \geq 0$.

This means that we can use an ordinary TTT plot based on $w_1 \leq w_2 \leq \dots \leq w_{n-1}$ to check a power law process assumption. If the power law process is a suitable model we expect the TTT plot to

Figure 5 A TTT plot based on the w_j values from a simulated power law process with $\beta = 0.5$ and sample size $n = 52$ [Data from Crow and Basu [22], © IEEE, 1992.]

wiggle around the diagonal since the TTT plot is an estimate of the corresponding scaled TTT transform, see Figure 5.

Figure 6 illustrates the TTT plot based on the w_j values obtained from data simulated from a nonhomogeneous Poisson process with intensity function $\rho(T) = \exp(T-1)$, which is not a power law process. From Figure 6 it is seen that the data is not in agreement with a power law process assumption since the plot behaves convexly and deviates much from the diagonal.

If the TTT plot is based on the w_j values from a renewal process, it is hard to separate the plot from a plot based on data from a power law process [23]. However, this shortcoming can be eliminated by using the transform

$$d_j = (n-j)(w_j - w_{j-1}) \text{ for } j = 1, 2, \dots, n-1 \quad (3)$$

sometimes called the *Durbin transform*. Barlow and Proschan [24] have proven that if $w_1 \leq w_2 \leq \dots \leq w_{n-1}$ is an ordered sample from an exponential distribution then also $d_1, d_2, \dots, d_{n-1}$ is an independent sample from an exponential distribution. This means that if we have times to failures $T_1, T_2, \dots, T_n$ from a power law process then the d_j values are independent observations from an exponential distribution. Accordingly, the TTT plot based on the d_j values

Figure 6 A TTT plot based on the w_j values from a simulated nonhomogeneous Poisson process with intensity function $\rho(T) = \exp(T - 1)$. This nonhomogeneous process is not a power law process and the plot is therefore expected to deviate from the diagonal [© IEEE, 1992.]

should wriggle around the diagonal in the unit square in the same manner as the plot based on the w_j values. See Klefsjö and Kumar [23] and Akersten *et al.* [25] for further discussion and illustration. Kvaløy and Lindqvist [26] also discuss trends in repairable systems data using the TTT concept.

Further TTT Plotting Applications

Extension of Power Law Process Testing

Another testing technique related to the power law process situation, presented by Akersten [27] is based on the fact that, with w_j as above, $w_1^\beta, w_2^\beta, \dots, w_n^\beta$ can be proven to be an ordered sample from a uniform distribution on $[0, 1]$. A consequence of this is that if the failures occur according to a power law process with power β , then the plot obtained by plotting and joining the points $(j/n, w_j^\beta)$, $j = 0, 1, \dots, n$ (where $w_0 = 0$), let us call it the w_j plot for short, is expected to twin around the diagonal in the unit square. By checking different values of β and choosing the one which gives the lowest value of a certain test statistic related to the cumulative TTT

statistic V [28], Akersten [27] obtains a possibility of both graphically and analytically testing a power law process assumption and also to estimate the value of β . Rigdon [29] also discusses test possibilities when studying power law processes.

In the case of a homogeneous Poisson process both the usual TTT plot and the w_j plot based on the points $(j/n, w_j)$ will tend to wriggle around the diagonal. If the failure history instead can be modeled by a nonhomogeneous Poisson process we expect the TTT plot based on the interevent times t_j to have a convex shape and the w_j plot to have a concave or convex shape depending on whether the intensity function is increasing or decreasing. If the TTT plot based on the interevent times has a concave shape, a nonhomogeneous Poisson process seems to be an incorrect assumption. See Akersten *et al.* [25] for more details.

Analysis of Test Statistics and Their Efficiency

The correspondence between the scaled TTT transform $\varphi(u)$ and different aging properties is a source for creating test statistics to analytically testing exponentiality against different aging properties and for studying the properties of these statistics. These issues are discussed e.g., by Klefsjö [30], Basu and Ebrahimi [31], Bergman and Klefsjö [32] and Bergman and Klefsjö [15]. For instance, Klefsjö [30] proved that the cumulative TTT statistic V introduced already by Barlow *et al.* [28] for testing exponentiality against IFR is consistent against all NBUE (New Better than Used in Expectation) life distributions, since V is a linear function of the area between the TTT plot and the diagonal. The TTT transform and TTT plot as an inspiration for efficiency calculations of test statistics is discussed in Bergman and Klefsjö [15]. In Klefsjö and Westberg [33] TTT transforms are used for a discussion of efficiency of a number of tests for exponentiality, among these Gnedenko's F-test [34].

TTT Plotting with Censored Data

The discussion above has focused on the situation when we have uncensored failure times. However, the TTT plotting positions j/n and u_j in the TTT plot for uncensored data can be expressed by using the empirical distribution function $F_n(t)$ and the empirical survival function $R_n(t) = 1 - F_n(t)$ as $(F_n(t_j), S_j/S_n)$;

Barlow and Campo [1]. This means that it is possible to generalize the TTT plotting technique to situations based on censored data by changing the empirical distribution function $F_n(t)$ to a suitable estimator of $F(t)$ based on the censored sample. One possibility then is to use the *Kaplan–Meier estimator (KME)*, whose properties were first studied by Kaplan and Meier [35]. Another one is to use the piecewise exponential estimator (PEXE) technique [36, 37]. A third idea is to use the *mean-order-number method* [38]. How to calculate and use TTT plotting with censored data is discussed e.g., in Westberg and Klefsjö [39], Westberg [40], Klefsjö and Westberg [33] and Sun and Kececioğlu [38].

Relation to the Lorenz Transform

Finally, we want to mention the close relation between the scaled TTT transform $\varphi(p)$ and the *Lorenz transform* $L(p)$, introduced by Lorenz [41] and frequently used in economics as a measure of concentration of wealth. The Lorenz transform is defined as

$$L(p) = \frac{1}{\mu} \int_0^p F^{-1}(s) ds \text{ for } 0 \leq p \leq 1 \quad (4)$$

which also is a curve within the unit square. Relations between the Lorenz curve and different aging properties of life distributions are discussed by e.g., Chandra and Singpurwalla [42], Klefsjö [43] and Perez-Ocun *et al.* [44]. Among other things, the *Gini Index (GI)*, often defined as twice the area between the egalitarian and the Lorenz transform, i.e.,

$$GI = 2 \int_0^1 (p - L(p)) dp \quad (5)$$

can be interpreted graphically as the area in the unit square above the scaled TTT transform. Applications of the Lorenz transform to repair problems are discussed by Dohi *et al.* [45].

TTT Plotting for Finding Active Effects in Design of Experiments

Bergman and Sandvik Wiklund [46] use the TTT plot to find active factors in **design of experiments**. A formal test is suggested based on the cumulative

TTT statistic V , see Barlow *et al.* [28], based on the squared contrasts.

Future Development

The TTT concept support some intuitive and insightful interpretations of life data and we foresee some future interesting applications.

Stationary Replacement Strategies

Introduction

Most equipment used in industry and in daily life are deteriorating; to avoid costly failures and repairs it is sometimes wise to replace or maintain them before failures. However, maintenance incurs costs and a balance between different kinds of maintenance costs and different kinds of costs incurred by failures has to be achieved. See e.g. Barlow and Hunter [1] and Barlow and Proschan [2]. Some older reviews are given by Pierskalla and Voelker [3] and Valdez-Flores and Feldman [4]; a rather recent one by Wang [5]. In **Replacement Strategies** a general discussion is given. Here, we will restrict ourselves to the case of stationary replacement strategies and when such replacement rules are optimal. A replacement strategy is stationary, if the decision rule π to replace equipment is dependent only on data obtained since the last replacement; for the new unit used as a replacement the same decision rule is applied. It is assumed that the stochastic features in the different replacement cycles are stochastically independent. The conditions for stationary replacement rules will be scrutinized. Finally, arguments against stationary replacement rules will be given.

Some Stationary Decision Rules

Cost Structures

Two major types of cost structures and corresponding objective functions are used in the discussion of stationary replacement rules: long run average cost per time unit and expected discounted cost with a constant discount rate, see **Replacement Strategies** and e.g. Taylor [6], Zuckerman [7, 8], Bergman [9], Nummelin [10], and Aven [11]. Assuming independence between units of equipment, i.e. between replacement cycles, it is easily seen that the objective function for both of these cost structures often

may be expressed as

$$B_T = \frac{E \left[\int_0^T a(t)h(t) dt + c(0) \right]}{E \left[\int_0^T a(t) dt + p(0) \right]} \quad (1)$$

where T is a stopping time based on the information about the condition of the system (and possibly some **randomization** experiment), $\{a(t)\}$ is a nondecreasing stochastic process, $\{h(t)\}$ is a nonnegative stochastic process and $c(0)$ and $p(0)$ are nonnegative random variables; all variables are adapted to the information about the condition of the equipment under study (possibly formulated as a filtration $F_t, t \geq 0$); see for instance, Bergman [12] and Aven and Bergman [13]. The stopping time T is interpreted as the replacement time.

For the average long run cost per time unit the numerator in equation (1) represents the expected cost associated with one replacement cycle and the denominator, the expected length of that cycle; the objective function (equation 1) is derived using a renewal argument. For discounted expected cost, a similar renewal argument applies with the denominator $E[(1 - \exp\{-\alpha T\})]$, where α is a positive discount factor, and the numerator is the expected discounted cost during one replacement cycle. More generally, the objective function (equation 1) is obtained for a number of other regenerative stopping problems; see for instance, Ross [14]. In Aven and Bergman [13] the corresponding optimization problem, i.e. how to find an optimal stopping time T , is considered. In fact, the minimization problem (equation 1) is solved by minimizing a sequence of λ -functions

$$\begin{aligned} C_\lambda^T &= E \left[\int_0^T a(t)h(t) dt + c(0) \right] \\ &\quad - \lambda E \left[\int_0^T h(t) dt + p(0) \right] \\ &= E \left[\int_0^T (a(t) - \lambda)h(t) dt + c(0) - \lambda p(0) \right] \end{aligned} \quad (2)$$

These functions are minimized by $T_\lambda = \inf\{t \geq 0; a(t) \geq \lambda\}$ for $\lambda \in (-\infty, \infty)$ assuming

$$E \left[\int_0^{T_\lambda} h(t) dt + p(0) \right] < \infty \quad (3)$$

2 Stationary Replacement Strategies

A general algorithm for the solution is provided in an appendix of Aven and Bergman [13]. Essentially, this algorithm states that if $\lambda_{n+1} = B_{T_{\lambda_n}}$ (for some starting value λ_1), then $\lambda_n \rightarrow \lambda^*$ and T_{λ^*} is an optimal replacement time. A similar result, however, slightly less general, is given by Nummelin [10] using a different technique. In Aven and Bergman [13] also a discrete version of the replacement problem is discussed.

Age Replacement

For age replacement we refer **Multivariate Age and Multivariate Renewal Replacement**; here we only note that, for the **estimation** of an optimal replacement with objective function average long run cost per time unit, it is possible to utilize the total time on test (TTT) plotting concept, a solution is indicated in **Total Time on Test Plots**, see also Bergman [15] and Bergman and Klefsjö [16].

Replacement on Condition

Owing to a number of reasons the different equipment of the same kind are aging very differently. The most important reason is that of a variable environment (see **Maintenance Optimization in Random Environments**), but also variations in the production process of equipment are of importance. Anyhow, in many situations it would be advantageous to have some measurements on the equipment and its condition and base the replacement decision on these measurements. In fact, this idea is the basis for applied maintenance planning as suggested by Nolan and Heap [17]. They had found, studying replacements and **preventive maintenance** at United Airlines, that the generally applied **maintenance policies** were much too expensive, as they were not taking into account the information available on the aging of components. They suggested that condition monitoring should be utilized wherever economically feasible. Their general approach is called *reliability-centred maintenance* and in the aerospace area the corresponding maintenance planning scheme is called *maintenance steering group-3* (MSG-3) see for instance, Sandberg and Stromberg [18].

Replacement strategies based on condition monitoring of a state variable $X(t)$, assuming a known probability model, have been studied by e.g. Taylor [6] and Feldman [19] where X is a jump process

with failures occurring only at a jump and with a failure probability depending on the entered state. In Bergman [9], a general wear process is assumed together with a state-dependent failure rate $v(x)$. It is possible to use the objective function (equation 1) in these cases.

In Bergman [15], an empirically driven solution to the replacement problem based on condition monitoring of studied equipment is given. This solution is similar to the one suggested for the age replacement problem in **Total Time on Test Plots** and Bergman and Klefsjö [16]. At that time, however, sensors were not that refined and the solution was not widely utilized. Today, however, data retrieving mechanisms have become much better and replacement solutions based on condition monitoring are feasible. This is also seen from an increasing number of industry supported theses presented in this area; see e.g. Backlund [20], Söderholm [21] and Svensson [22].

Replacement of Repairable Systems

In some studies, (see e.g. Stadge and Zuckerman [23], Boshuizen [24], and Sandve and Aven [25]) the systems under study are assumed to be possible to repair minimally (see **General Minimal Repair Models**). Also in these cases it is possible to utilize the general framework introduced above.

Concluding Remarks

The idea of stationary replacement rules might be good as a basis for understanding the general replacement problem. However, it is assumed that the probability models are known from the beginning. In reality, that is almost never the case. Rather, it is important that we allow for learning in the strategies utilized. That leads to adaptive replacement strategies where successively obtained information about the failure model is obtained. The Bayesian approach is then a natural framework, see e.g. Mazzuchi and Soyer [26], Sheu *et al.* [27], and **Maintenance Optimization**. Stationary replacement strategies will not apply in this case.

Maintenance Optimization in Random Environments

Introduction

In this article, we focus on a number of optimal management problems involving reliability and risk models operating in a random environment. The environment is described by a stochastic process, which represents important factors that affect the stochastic and deterministic parameters of the reliability or risk model. The term *environment* is used in the generic sense so that it represents any set of conditions that affect the stochastic structure of the model investigated. The concept of an “environmental” process, in one form or another, has been used in earlier literature for various purposes. Neveu [1] provides an early reference to paired stochastic processes where the first component is a Markov process while the second one has conditionally independent increments given the first. Ezhov and Skorohod [2] refer to this as a Markov process with a homogeneous second component. In a more modern setting, Çınlar [3, 4] introduced Markov additive processes and provided a detailed description on the structure of the additive component. The environment is modeled as a Markov process in all these cases and the additive process represents the stochastic evolution of a quantity of interest. Since the model parameters depend on the state of the environment at any time, the environmental process is also a process that modulates the model. As the state of the environment changes randomly, so do the model parameters and the environmental process indirectly generates the variation in the parameters.

The use of a modulating stochastic process as a source of variation in the model parameters and of dependence among the model components has proved to be quite useful in operations research and management science applications. In modeling hardware reliability for complex devices consisting of many interdependent components, the concept was introduced by Çınlar and Özekici [5] where the failure rate and hazard functions of the components all depend on the prevailing environmental conditions. For example, a complex device like a jet engine

consists of a large number of components where the failure structure of each component depends very much on the set of environmental conditions that it is subjected to during flight. The levels of vibration, atmospheric pressure, temperature, and so on, obviously change during take-off, cruising, and landing. Component lifetimes and reliabilities depend on these random environmental variations. Moreover, the components have dependent lifetimes since they operate in the same environment. The concept of random hazard functions is also used in Gaver [6] and Arjas [7]. The intrinsic aging model of Çınlar and Özekici [5] is studied further in Çınlar *et al.* [8] to determine the conditions that lead to associated component lifetimes, as well as multivariate increasing failure rate (IFR) and new better than used (NBU) life distribution characterizations. It was also extended in Shaked and Shanthikumar [9] by discussions on several different models with multicomponent replacement policies. Lindley and Singpurwalla [10] discuss the effects of the random environment on the reliability of a system consisting of components which share the same environment. Although the initial state of the environment is random, they assume that it remains constant in time and components have exponential life distributions in each possible environment. This model is also studied by Lefèvre and Malice [11] to determine partial orderings on the number of functioning components and the reliability of k -out-of- n systems, for different partial orderings of the probability distribution on the environmental state. The association of the lifetimes of components subjected to a randomly varying environment is discussed in Lefèvre and Milhaud [12]. Singpurwalla and Youngren [13] also discuss multivariate distributions that arise in models where a dynamic environment affects the failure rates of the components.

Although we discuss the use of environmental processes in managing hardware as well as **software reliability** and risk models, there is now considerable amount of literature on modulation in a variety of applications. An example in queuing is provided by Prabhu and Zhu [14] where customer arrival and service rates are modulated by a Markov process. Song and Zipkin [15] consider an inventory model with a demand process that fluctuates with respect to stochastically changing economic conditions. A general discussion on the idea can be found in Özekici [16]. The interested reader is referred to

Asmussen [17] and Rolski *et al.* [18] for further applications in queuing, insurance, and finance.

The stochastic structure of a rather general environmental process involving a **Markov renewal** process is described in the section titled “The Environmental Process”. Issues regarding the maintenance of complex systems under random environments are discussed in the section titled “Maintenance of Complex Systems”, and the last section presents some results on the structure of optimal **maintenance policies**.

The Environmental Process

We suppose that the environmental process is quite general as given in Çekyay and Özekici [19] (*see Markov Renewal Processes in Reliability Modeling*). Let T_n denote the time of the n th environment change and X_n denote the n th environmental state with $T_0 \equiv 0$. The main assumption is that the process $(X, T) = \{(X_n, T_n); n \geq 0\}$ is a Markov renewal process on the state space E with some semi-Markov kernel Q . Moreover, the environmental process $Y = \{Y_t; t \geq 0\}$ is the minimal semi-Markov process associated with (X, T) so that Y_t is the state of the environment at time t . More precisely, $Y_t = X_n$ whenever $T_n \leq t < T_{n+1}$. For any $i, j \in E$ and $t \geq 0$,

$$Q(i, j, t) = P\{X_{n+1} = j, T_{n+1} - T_n \leq t | X_n = i\} \quad (1)$$

and it is well-known that X is a Markov chain on E with transition matrix $P(i, j) = P\{X_{n+1} = j | X_n = i\} = Q(i, j, +\infty)$. We further assume that the Markov renewal process has infinite lifetime so that $\sup_n T_n = +\infty$. The probabilistic structure of T is given by the conditional distributions

$$\begin{aligned} G(i, j, t) &= P\{T_{n+1} - T_n \leq t | X_n = i, X_{n+1} = j\} \\ &= \frac{Q(i, j, t)}{P(i, j)} \end{aligned} \quad (2)$$

for $P(i, j) > 0$. Moreover, it is easy to see that

$$F_i(t) = P_i\{T_1 \leq t\} = \sum_{j \in E} Q(i, j, t) \quad (3)$$

denotes the distribution of the duration of state i .

Maintenance of Complex Systems

A complex system consists of many components that have stochastically dependent lifetimes. This dependence is induced by the common environment that they all operate in. Moreover, there is usually some economic dependence among the components due to the economies of scale obtained by maintaining many components at the same time. The most common type of maintenance involves the replacement of some of the functioning and nonfunctional components. The problem is to determine when replacement should be done and which components to replace. This should of course be done by observing the state of the reliability system. The intrinsic aging model introduced by Çınlar and Özekici [5] is a tractable one since it provides a realistic and simple stochastic structure of complex systems with many components. In Çekyay and Özekici [19], the authors consider various issues regarding reliability of such systems under the assumption that there is either no repair or maximal repair when all components are replaced at the beginning of each environmental state. In particular, the system reliability for the two cases are characterized through Markov renewal equations (15) and (37) in Çekyay and Özekici [19]. We will now extend their analysis by considering what happens when one incorporates a decision making process in their setting. We will follow their notation and terminology and the reader should first read that chapter. In particular, we set $R_+ = [0, \infty)$ and $F = R_+^m$ where m is the number of components. Moreover, we assume throughout that the components are serially connected so that the system fails as soon as any one of the components fails.

The intrinsic aging model is described by equations (25)–(33) in Çekyay and Özekici [19]. Recall that for any component k , $H_k(i, \cdot)$ is the cumulative hazard function and $r_k(i, \cdot)$ is the intrinsic aging rate function in environment i . The intrinsic age process is defined through the differential equation $dA_t(k)/dt = r_k(Y_t, A_t(k))$. The age of the system is $A_t = (A_t(1), A_t(2), \dots, A_t(m))$ at time t . It is clear that the process A takes values in F . Whenever the state of the environment changes at time T_n there is a decision made on maintenance based on the observation of the new environment X_n and intrinsic age $B_n = A_{T_n}$ of the system. The primary process is now given by the new Markov renewal process $((X, B), T)$.

We propose to use policies given by sets $M \subseteq E \times F$ so that **preventive maintenance** is done at the first-passage time

$$T_M = \inf\{T_n : (X_n, B_n) \in M\} \quad (4)$$

when the system is maintained if the observed environmental state i and the intrinsic ages $a = (a_1, a_2, \dots, a_m)$ of the components satisfy $(i, a) \in M$. The stopping time equation (4) identifies the time of maintenance. The type of maintenance to be done is another issue. The most common type involves replacements where one can replace either all components, or only a given a set of components, or only those that have failed. One can also use a repair type of policy where instead of replacing a component by a brand-new one, one repairs it to a lower intrinsic age level. A typical policy in this regard is the **minimal repair** one when a failed component is given a jump start and brought back to the working condition or age just before failure.

For any such policy, Çinlar and Özekici [5] make a Markov renewal argument to obtain the characterization

$$\begin{aligned} P_{ia}\{L > T_M\} &= \sum_{j \in E} \int_F \bar{R}(i, a; j, db) \\ &\quad \times \sum_{k \in E} \int_{R_+} Q(j, k, ds) e^{-\sigma(h(k, b, s) - b)} \\ &\quad \times 1_M(k, h(k, b, s)) \end{aligned} \quad (5)$$

for $(i, a) \notin M$ where $1_M(y)$ is the indicator function that is equal to 1 if and only if $y \in M$, and $\bar{R} = \sum_n \bar{P}^n$ is the potential kernel corresponding to the defective transition kernel

$$\begin{aligned} \bar{P}(i, a; j, db) &= \int_{R_+} Q(i, j, ds) H(i, a, s, db) \\ &\quad \times e^{-\sigma(b-a)} 1_{M^c}(j, b) \end{aligned} \quad (6)$$

where M^c denotes the complement of M . Note that equation (5) gives the probability that there is no system failure before the time of maintenance. The probability $P_{ia}\{L > t\}$ that the system does not fail until time t is already determined by equations (15) and (37) in Çekyay and Özekici [19] for the two extreme cases of no repair ($M = \phi$ and no preventive

replacement is done) and maximal repair ($M = E \times R_+^m$ and all components are replaced), respectively.

If $L(k)$ is the lifetime of the k th component, and L is the lifetime of the system, then $L = \min\{L(k); k = 1, 2, \dots, m\}$ and

$$S = \min\{T_M, L\} \quad (7)$$

is the first time either maintenance is done or the system fails, whichever occurs sooner. Then, using Markov renewal theory one obtains the joint distribution

$$\begin{aligned} P_{ia}\{X_S = j, A_S \in db, S \leq t, S = L(k)\} \\ = \sum_{l \in E} \int_{F \times [0, t]} \tilde{R}(i, a; l, dc; ds) \int_{[0, t-s]} du \bar{F}_l(u) \\ \times I(l, j) H(l, c, u; db) e^{-\sigma(b-c)} r_k(l, b) \end{aligned} \quad (8)$$

for $(i, a) \notin M$ where $\tilde{R} = \sum_n \tilde{Q}^n$ is the Markov renewal kernel corresponding to the semi-Markov kernel

$$\begin{aligned} \tilde{Q}(i, a; j, db; ds) &= Q(i, j, ds) H(i, a, s; db) \\ &\quad \times e^{-\sigma(b-a)} 1_{M^c}(j, b) \end{aligned} \quad (9)$$

and r_k is the intrinsic aging rate function given by equation (25) in Çekyay and Özekici [19]. Using a similar analysis, one also obtains

$$\begin{aligned} P_{ia}\{X_S = j, A_S \in db, S \leq t, S = T_M\} \\ = \sum_{l \in E} \int_{F \times [0, t]} \tilde{R}(i, a; l, dc; ds) \int_{[0, t-s]} Q(l, j, du) \\ \times H(l, c, u; db) e^{-\sigma(b-c)} 1_M(j, b) \end{aligned} \quad (10)$$

for $(i, a) \notin M$. In these expressions, equation (8) gives the probability that the system fails before time t due to the failure of component k in environmental state j at age db , while equation (10) gives the probability that the system is maintained before it fails until time t in environmental state j at age db . Both solutions are of the form $\tilde{R} * g$ for an appropriate function g . The sum of equation (8) for all k and equation (10) provides another Markov renewal characterization for the probability that preventive or failure maintenance is done before time t in environmental state j at age db . The probabilities (5), (8),

and (10) provide important performance measures to the decision maker to choose maintenance policies.

We will not attempt to formulate an optimization problem in our setting to determine optimal maintenance policies. It is indeed an interesting problem which has not been analyzed before for models with intrinsic aging in random environments depicted by a Markov renewal process. This will undoubtedly require various cost figures on system and component failures as well as costs of maintenance. We should point out, however, that the structure of optimal policies is by no means trivial and intuitive. The formulation of the optimization problem, the characterization of optimal policies, and the solution procedure is quite complicated. It is well known that the structure of optimal policies may be quite complex in multicomponent systems even when there are no environmental fluctuations. Preventive replacement is perhaps the most widely used maintenance policy to prevent the device from failure during operation, thus incurring excessive failure costs. The fixed environment case with several cost structures and objectives is discussed extensively in the literature by many authors and, in most cases, an age-replacement policy is optimal if the life distribution is IFR. Özekici [20] provides an example along this direction and a discussion on the optimality conditions for control-limit policies can be found in So [21].

Structure of Optimal Policies

In the optimal replacement problem, for example, perhaps the most widely used policy is the age-replacement policy where a component is replaced when its age is observed to be over a critical level. The problem then is to determine these ages optimally in order to minimize the average cost or total cost. A simple age replacement policy is one in which, in any environment i , there is critical age vector b_i such that component k is replaced if and only if the intrinsic age of the component exceeds $b_i(k)$. This policy is specified by m critical thresholds for each environment. However, such a policy is not necessarily optimal. It is clear that the component lifetimes are stochastically dependent due to their common environment. This implies that a component may be more prone to failure if the age of another component is higher and the critical threshold may depend on the age of other components. Another

complication is due to economic dependence among the components. This is the case when there is a fixed cost of replacement such that one is tempted to replace a functioning component when a failed component must be replaced since the fixed cost is already paid. In such cases, so-called opportunistic replacement policies with rather complex structures may be optimal. Özekici [22, 23] demonstrates this through several examples. For simplicity, suppose that there are two components only so that the optimal policy can be identified by the ages at which only component 1 is replaced (1), or only component 2 is replaced (2), or both components are replaced (1,2), or no component is replaced (0). Figure 1 depicts a typical optimal policy.

It is clear that the structure of the optimal policy, in general, is nontrivial and it cannot be identified by a few critical numbers. This is actually due to two reasons: economic and stochastic dependence among the components. Some rather counterintuitive observations can be made on Figure 1. For example, at point B, no component should be replaced but at point A, where there is substantial aging on component 2, both 1 and 2 should be replaced even though component 1 is at the same age as point B. This is called *opportunistic replacement* since 1 is replaced by making use of the opportunity in replacing component 2. Since an “old” component 2 is being replaced optimally, it may be best to replace component 1 at the same time. Opportunistic replacement is due to the fact that $b_1 \leq c_1$ and $b_2 \leq c_2$. This could be further clarified by considering the case where the components are stochastically independent while 1 has an exponentially distributed lifetime and

Figure 1 Optimal policy for 2 components

Figure 2 Optimal policy when one component has exponential lifetime

2 has an IFR life distribution. If the components are economically dependent, Radner and Jorgenson [24] showed that the optimal policy has the simple form given in Figure 2 for a fixed environment model. Note that component 1 is replaced only at failure (F) since it has an exponential lifetime. Component 2 is optimally replaced at the critical age c_2 , but if component 1 has failed and must be replaced, then 2 can be replaced opportunistically as early as age $b_2 \leq c_2$.

Another interesting observation follows from the comparison of points C and D on Figure 1. Note that component 1 is replaced at C but not at the “older” system age D. The system is not interfered with at the “worse” state D while a replacement decision is given at C. This is due to “opportunistic nonreplacement” since it may be best not to do any replacement at D and wait a little longer to replace both 1 and 2 at the same time.

The complexity in the structure of the optimal replacement policy creates computational as well as practical difficulties since it is not identified by a few critical numbers. Even if the optimal policy is determined by any one of the procedures, its implementation requires extreme precision. For these reasons, one may have to approximate the optimal policy by one that has a much simpler structure. An example is given by Van der Duyn Schouten, and Vanneste [25] analyzed the (n, N) policy given in Figure 3.

Note that the (n, N) policy provides substantial simplification when compared with the optimal policy in Figure 1. The fact that $n_1 \leq N_1$ and $n_2 \leq N_2$ show that, in essence, these policies reflect the existence of opportunistic replacement. However, this does not allow for “opportunistic nonreplacement” since the

Figure 3 (n, N) policy

number of components replaced in an “older” system is at least as many as that of a “younger” system.

Group Maintenance Policies

Maintenance Policies

Suppose that n machines are operating in parallel. A loss of c_d per unit time is incurred for each failed machine. The cost of replacing a broken machine with a new machine is denoted by c_b , while the cost of servicing a working machine to be “as good as new” is given by c_r . A fixed cost of c_0 is incurred each time replacement or servicing of machines occurs. In this paper group replacement and servicing strategies are considered. The failure times of the machines are assumed to be independent identically distributed random variables with increasing hazard rate and density function $f(\bullet)$. The random variable representing the life length of a machine will be denoted by X .

A number of group replacement policies have appeared in the literature. An m -failure policy calls for group replacement at the m th failure (see Assaf and Shantikumar [1], Nakagawa [2], Park [3], Wilson and Benmerzouga [4]). T -age group replacement policies call for group replacement whenever the system reaches age T (see, e.g., Okumoto and Elsayed [5]). Ritchken and Wilson [6] introduce a class of policies, called (m, T) **group maintenance policies**, that call for group replacement at the m th failure or time T , whichever occurs first; Benmerzouga and Harous [7], a class of policies called $(m\text{-failure}, P\text{-repairmen})$ **group maintenance policies**, that call for group replacement at the m th failure with P -repairmen in the crew. Wilson and Benmerzouga [8] consider the case where the underlying failure distribution is exponential with an unknown parameter that must be estimated from the operation of the machines. A more general form of this policy for the case of three machines operating in parallel is considered by Wilson and Popova [9]. The case of phase distributed failure times has been analyzed by Wilson and Popova [9]. Mazzuchi and Soyer consider the case of a single machine with a Weibull failure time [11].

The m -failure, T -age, and (m, T) group replacement policies have one managerially unpalatable drawback: they ignore what happens during the cycle until the m th failure or time T has occurred. For

instance, consider a problem where 100 machines are operating in parallel and the optimal m -failure policy is to replace whenever the 51st machine breaks down. Consider the following two cases: the first 51 machines fail 1 year after being put into operation; 50 machines fail on the second day of operation and the 51st fails 1 year after the start of the cycle. The 51-failure policy treats the above two cases in exactly the same manner – group replacement is performed after 1 year of operation. However, most decision makers would want to treat the above two situations in a completely different manner. Of course, the analysis that would have provided the 51-failure policy as the optimal m -failure policy is based on average cost per unit time over an infinite horizon. Even though the cost of carrying 50 nonfunctioning machines for 1 year might be very large, the probability of such an event occurring would be so low that this case would be essentially disregarded in the average per unit time analysis. However, events of low probability can occur. Although it might be reasonable to discount them *a priori*, it would be foolish to ignore them if they actually occur. Assuming continuous inspection, this paper provides an easily implemented replacement policy that takes account of the actual state of the system at each stage.

Define a decision rule δ to be a function from $\{(i, x): 0 \leq i \leq n, 0 \leq x \leq \infty\}$, into the closed interval $[0, 1]$, where $\delta(i, x)$ denotes the probability with which group replacement will be made, if exactly i machines are broken and it has been x time units since the last group replacement. This class of strategies includes the m -failure, T -age and (m, T) policies as special cases. An m -failure policy is obtained by requiring $\delta(i, x)$ to equal 1 if $i \geq m$ and to equal 0, otherwise. A T -age replacement policy is obtained by setting $\delta(i, x)$ to equal 1 for $x \geq T$ and equal to 0, otherwise. An (m, T) policy is obtained by defining δ to satisfy

$$\delta(i, x) = \begin{cases} 1 & \text{if } i \geq m \\ 1 & \text{if } x \geq T \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

Implementation of a policy δ as defined above only requires knowledge of the current state (i, x) . Thus no extra information, other than normally available when using an m -failure policy, is required. However, finding the optimal m -failure policy is relatively straightforward. Finding a policy δ that is optimal or ε -optimal (a discretized solution within ε of the true

2 Group Maintenance Policies

optimal) is not quite so straightforward. However, once such a policy has been found, implementation is not much harder than it would be for m -failure, T -age, or (m, T) policies.

The section titled “Optimal Policies When System is Observed at a Fixed Number of Times” provides a procedure for finding an optimal replacement policy when decisions can only be made at times $x_1 < x_2 < \dots < x_m$. As $x_m \rightarrow \infty$ and $\max_j |x_{j+1} - x_j| \rightarrow 0$, the cost associated with the policy computed using this assumption converges to the cost of the optimal policy for the case where decisions are allowed at anytime. The section titled “Continuous Observation” contains a procedure that will produce lower bounds on the optimal cost.

Optimal Policies When System is Observed at a Fixed Number of Times

In this section, the case where the state of the system is only observed at the fixed times $0 = x_0 < x_1 < x_2 < \dots < x_m$ is considered. It will be assumed that all machines will be replaced no later than time x_m and that none are replaced before time x_1 . The process is defined to be in state (i, x_j) if the current time is given by x_j and exactly i machines are broken.

In the section titled “Transition Probabilities and Costs”, the transition probabilities and costs of moving between states will be derived while the section titled “Policies” contains a description of the space of policies that will be considered. The section titled “An LP Formulation When the Expected Cycle Time is Provided” contains a linear programming (LP) formulation that will provide the best policy with a specified expected cycle time. (The LP approach adopted is similar to that described in Heyman and Sobel [12].) A search method over the expected cycle time then yields policies that are ε -optimal.

Transition Probabilities and Costs

At a given state, one of two actions must be taken: replace and/or repair all machines to as good as new ($a = 1$); wait until the next state ($a = 0$). Define $F_j(x)$ to be the conditional distribution function $P[X \leq x | X > x_j]$. For $j \geq 1$, define $P_{k,j-1}^{i,j}$ to be the probability that exactly i machines are broken at time x_j given that $k \leq i$ were broken at time x_{j-1} , i.e.,

$$P_{k,j-1}^{i,j} = \binom{n-k}{i-k} \{F(x_{j+1}|x_j)\}^{i-k} \times \{1 - F(x_{j+1}|x_j)\}^{n-i} \quad (2)$$

Let c_{ija} , $a \in \{0, 1\}$ denote the expected cost incurred while the process moves from state (i, x_j) to the next state if action a is taken. If the action is to perform group replacement then the cost consists of two machines: the cost of purchasing replacement machines for those that have failed and the cost of performing maintenance on the machines that are still working. Thus, $c_{ij1} = c_0 + ic_b + (n-i)c_r$. Now suppose that replacement is not performed at state (i, x_j) . The cost incurred between time x_j and x_{j+1} will consist of two parts: the downtime for the i machines that have failed by time x_j and the downtime for any machine that fails between x_j and x_{j+1} . The expected downtime over the period x_j to x_{j+1} for any one of the machines working at time x_j is given by $x_{j+1} - E[\min(x_{j+1}, X) | X > x_j] = \int_{x_j}^{x_{j+1}} F_j(x) dx$. Thus, the immediate expected cost of continuing at state (i, x_j) is given by

$$c_{ij0} = ic_d(x_{j+1} - x_j) + (n-i)c_d \int_{x_j}^{x_{j+1}} F_j(x) dx \quad (3)$$

where the first term is the downtime cost of the i machines that are broken at time x_j and the second term is the expected downtime cost for machines that fail between x_j and x_{j+1} . Thus, the costs c_{ija} can be written as follows:

$$c_{ija} = \begin{cases} c_0 + ic_b + (n-i)c_r & \text{for } a = 1 \\ ic_d(x_{j+1} - x_j) + (n-i)c_d \int_{x_j}^{x_{j+1}} F_j(x) dx & \text{for } a = 0 \end{cases} \quad (4)$$

Policies

A randomized policy δ is a function from $\{(i, x_j) : 0 \leq i \leq n, 1 \leq j \leq m\}$ to the interval $[0, 1]$. Here, $\delta(i, x_j) \in [0, 1]$ is to be interpreted as the probability with which the decision maker will perform group replacement. Set $\delta(i, x_m) \equiv 1$ for all i (i.e., no matter how many machines are working, replacement is required at time x_m).

Assume that the randomized policy δ is to be used. A cycle is defined to be the period between group replacements. Let $K(\delta)$, $C(\delta)$, and $T(\delta)$, respectively, denote the random variables for the cost per unit time, the cycle cost and the cycle length for a policy δ . Then, from the Renewal Reward theorem in terms of

expected values,

$$E[K(\delta)] = \frac{E[C(\delta)]}{E[T(\delta)]} \quad (5)$$

For purposes of mathematical convenience, the analysis that follows will be for this general class of randomized strategies. However, the solution procedure will always produce a deterministic policy. (This can be seen by applying the following argument from decision theory. Suppose $\delta^*(.,.)$ is an optimal policy with $0 < \delta^*(i_0, x_{j_0}) < 1$ for some i_0 and j_0 . Define two new policies, $\delta^1(.,.)$ and $\delta^2(.,.)$ to be identical to $\delta^*(.,.)$ except that at the state (i_0, x_{j_0}) , $\delta^1(i_0, x_{j_0})$ equals 0 while $\delta^2(i_0, x_{j_0})$ equals 1, i.e., $\delta^1(.,.)$ and $\delta^2(.,.)$ are nonrandomized at (i_0, x_{j_0}) . Now suppose that, at the beginning of each cycle, the decision maker chooses to implement either policy $\delta^1(.,.)$ with probability $1 - \delta^*(i_0, x_{j_0})$ or policy $\delta^2(.,.)$ with probability $\delta^*(i_0, x_{j_0})$. The expected cost per unit time of this procedure equals

$$\frac{(1 - \delta^*(i_0, x_{j_0}))E[C(\delta^1)] + \delta^*(i_0, x_{j_0})E[C(\delta^2)]}{(1 - \delta^*(i_0, x_{j_0}))E[T(\delta^1)] + \delta^*(i_0, x_{j_0})E[T(\delta^2)]} \quad (6)$$

which, by construction, equals $E[(\delta^*)]$. Note that

$$\frac{(1 - z)E[C(\delta^1)] + zE[C(\delta^2)]}{(1 - z)E[T(\delta^1)] + zE[T(\delta^2)]} \quad (7)$$

is a monotonic function of z for $z \in [0, 1]$ that equals $E[K(\delta^1)]$ at $z = 0$ and $E[K(\delta^2)]$ at $z = 1$.

Consequently,

$$E[K(\delta^*)] \geq \min\{E[K(\delta^1)], E[K(\delta^2)]\} \quad (8)$$

So, an optimal policy is given by either $\delta^1(.,.)$ or $\delta^2(.,.)$, neither of which is randomized at (i_0, x_{j_0}) . Now repeat this argument for any other state for which $0 < \delta^*(i, x_j) < 1$.

An LP Formulation When the Expected Cycle Time is Provided

Let $p_{ij0}(\delta)$ denote the probability that the state (i, x_j) will be visited during the cycle and the decision not to replace the system at that time is made. Let $p_{ij1}(\delta)$ denote the probability that the process will visit the state (i, x_j) and the decision to replace all machines is made.

The expected cost per cycle can be written as $c_{000} + \sum c_{ija} p_{ija}(\delta)$. For $j \geq 1$, let ℓ_{ija} be the transition time from state (i, x_j) to the next state when action a is taken, i.e.,

$$\ell_{ija} = \begin{cases} x_{j+1} - x_j & \text{for } a = 0 \\ 0 & \text{for } a = 1 \end{cases} \quad (9)$$

Then the expected cost per unit time from following the policy δ is given by

$$E[K(\delta)] = \frac{c_{000} + \sum_{i,j \geq 1,a} c_{ija} p_{ija}(\delta)}{x_1} + \sum_{i,j \geq 1,a} \ell_{ija} p_{ija}(\delta) \quad (10)$$

Theorem 1 shows that, given a policy with a specific value for the expected cycle length, the expected cost per unit time can be written in a linear form with linear constraints with appropriately chosen variables. In Theorem 2, it is shown that any such formulation leads to a policy with the specified expected cycle time.

Theorem 1 *Let $\delta(.,.)$ be any given policy that calls for replacement no sooner than x_1 . Denote the expected length of the cycle using this policy by B . Then the expected cost per unit time associated with this policy can be written in the form*

$$\frac{c_{000}}{B} + \sum_{i,j \geq 1,a} c_{ija} y_{ija} \quad (11)$$

where $i \in \{0, \dots, n\}$, $j \in \{1, 2, \dots, m\}$, $a \in \{0, 1\}$ and y_{ija} satisfy the following constraints:

$$y_{ija} \geq 0 \forall i, j, a \quad (12)$$

$$\frac{x_1}{B} + \sum_{i,j,a} \ell_{ija} y_{ija} = 1 \quad (13)$$

$$y_{ij0} + y_{ij1} = \sum_{k \leq i} P_{k,j-1}^{i-k,j} y_{i(j-1)0}$$

$$\text{for } j \geq 2 \text{ and } i \in \{1, \dots, n\} \quad (14)$$

$$y_{i10} + y_{i11} = B^{-1} P_{0,0}^{i,1} \text{ for } i = \{1, \dots, n\} \quad (15)$$

Proof. The expected length, $E[T(\delta)]$, of the renewal cycle when the policy δ is used is given by

$$B = E[T(\delta)] = x_1 + \sum_{i,j \geq 1,a} \ell_{ija} p_{ija}(\delta) \quad (16)$$

4 Group Maintenance Policies

For $j \geq 1$, define the quantities y_{ija} as follows:

$$y_{ija} \equiv \frac{p_{ija}}{E[T(\delta)]} \quad (17)$$

Then the expected cost per unit time can be written as

$$\begin{aligned} \frac{c_{000}}{E[T(\delta)]} + \sum_{i,j \geq 1,a} \frac{c_{ija} p_{ija}}{E[T(\delta)]} \\ = \frac{c_{000}}{B} + \sum_{i,j \geq 1,a} c_{ija} y_{ija} \end{aligned} \quad (18)$$

The quantities y_{ija} must satisfy a number of constraints. Since $p_{ija}(\delta) \geq 0$ and $x_1 + \sum_{i,j \geq 1,a} \ell_{ija} p_{ija}(\delta) \equiv E[T(\delta)] = B$, the quantities y_{ija} must satisfy equations (12) and (13).

The probability that the process visits state (i, x_j) during a cycle is given by $p_{ij0}(\delta) + p_{ij1}(\delta)$. The process can only be in this state if $k \leq i$ machines were broken at time x_{j-1} , action $a = 0$ was taken, and exactly $i - k$ machines broke down during the period from time x_{j-1} to x_j . Thus, for $j \geq 2$, the quantities $p_{ija}(\delta)$ must satisfy

$$p_{ij0}(\delta) + p_{ij1}(\delta) = \sum_{k \leq i} P_{k,j-1}^{i-k,j} p_{k(j-1)0}(\delta) \quad (19)$$

On dividing the above expression by $E[T(\delta)]$, the quantities y_{ija} are seen to satisfy equation (14).

Between times 0 and x_1 , i machines fail with probability equal $P_{0,0}^{i,1}$. Equation (15) follows on noting that

$$p_{i10}(\delta) + p_{i11}(\delta) = P_{0,0}^{i,1} \quad (20)$$

and dividing across by B .

Theorem 2 For a given B with $B \geq x_1$, suppose that y_{ija} for $i \in \{0, 1, 2, \dots, n\}$, $j \in \{1, \dots, m\}$, and $a \in \{0, 1\}$ satisfy the following:

$$y_{ija} \geq 0 \forall i, j, a \quad (21)$$

$$\frac{x_1}{B} + \sum_{i,j \geq 1,a} \ell_{ija} y_{ija} = 1 \quad (22)$$

$$\begin{aligned} y_{ij0} + y_{ij1} &= \sum_{k \leq i} P_{k,j-1}^{i-k,j} y_{i(j-1)0} \\ \text{for } j \geq 2 \text{ and } i \in \{0, \dots, n\} \end{aligned} \quad (23)$$

$$y_{i10} + y_{i11} = B^{-1} P_{0,0}^{i,1} \text{ for } i \in \{0, \dots, n\} \quad (24)$$

Define a group replacement policy, $\delta(.,.)$ as follows:

$$\delta(i, x_j) = \frac{y_{ij1}}{y_{ij0} + y_{ij1}}, \forall i, j \quad (25)$$

i.e., if i machines are down at time x_j , replace the system with probability equal to $y_{ij1}/(y_{ij0} + y_{ij1})$.

Then,

$$E[T(\delta)] = B \quad (26)$$

and

$$E[K(\delta)] = \frac{c_{000}}{B} + \sum_{i,j \geq 1,a} c_{ija} y_{ija} \quad (27)$$

Proof. First for $j \geq 1$, it will be shown that for a given cycle, the fraction of time i machines are down and decision a is taken at time x_j , is given by

$$p_{ija} = B y_{ija} \quad (28)$$

The proof will be by induction on j . First consider the case $j = 1$. At time x_1 , the probability that exactly i machines are down is given by $P_{0,0}^{i,1}$. Replacement will occur with probability equal to $\delta(i, x_1)$. Thus, using equation (25),

$$p_{i1a}(\delta) = \begin{cases} P_{0,0}^{i,1} \delta(i, 1) = \frac{P_{0,0}^{i,1} y_{i11}}{(y_{i10} + y_{i11})} \\ \text{for } a = 1 \\ P_{0,0}^{i,1} \{1 - \delta(i, 1)\} = \frac{P_{0,0}^{i,1} y_{i10}}{(y_{i10} + y_{i11})} \\ \text{for } a = 0 \end{cases} \quad (29)$$

Now use equation (24) in equation (29) to see that

$$p_{i1a} = B y_{i1a} \quad (30)$$

as required.

Now assume that equation (28) is true for $j - 1$. The goal is to show that this implies that equation (28) is true for j .

For i machines to be down at time x_j , $k \leq i$ machines must have been down at time x_{j-1} , the decision to continue was made at time x_{j-1} and $i - k$ must have failed between times x_{j-1} and x_j . A decision to replace will be made with probability $\delta(i, j)$. Thus,

$$p_{ija}(\delta) = \begin{cases} \delta(i, j) \sum_{k \leq i} P_{k,j-1}^{i-k,j} p_{k(j-1)0} \\ \text{for } a = 1 \\ (1 - \delta(i, j)) \sum_{k \leq i} P_{k,j-1}^{i-k,j} p_{k(j-1)0} \\ \text{for } a = 0 \end{cases} \quad (31)$$

Now use the induction hypothesis to replace $p_{k(j-1)0}$ with $y_{k(j-1)0}/B$ in equation (31) to see that

$$p_{ija}(\delta) = \begin{cases} \delta(i, j) B \sum_{k \leq i} P_{k, j-1}^{i, -k, j} y_{k(j-1)0} & \text{for } a = 1 \\ (1 - \delta(i, j)) B \sum_{k \leq i} P_{k, j-1}^{i, -k, j} y_{k(j-1)0} & \text{for } a = 0 \end{cases} \quad (32)$$

Use equation (23) and the definition of $\delta(i, j)$ to see that $p_{ija} = B y_{ija}$ as required.

From equations (22) and (28) the definition of expected cycle time:

$$\begin{aligned} E[T(\delta)] &= x_1 + \sum_{i, j \geq 1, a} \ell_{ija} p_{ija}(\delta) \\ &= x_1 + B \sum_{i, j \geq 1, a} \ell_{ija} y_{ija} \\ &= B \end{aligned} \quad (33)$$

as required.

From the above, equations (10) and (28), the expected cost associated with $\delta(., .)$ is given by

$$\begin{aligned} E[K(\delta)] &= \frac{c_{000} + \sum_{i, j \geq 1, a} c_{ija}(\delta) p_{ija}(\delta)}{E[T(\delta)]} \\ &= \frac{c_{000} + \sum_{i, j \geq 1, a} c_{ija}(\delta) p_{ija}}{B} \\ &= \frac{c_{000}}{B} + \sum_{i, j \geq 1, a} c_{ija}(\delta) y_{ija} \end{aligned} \quad (34)$$

as required.

Example Suppose there are six machines with i.i.d. $\gamma(\alpha = 5, \beta = 5)$ distributed failure times with costs as shown in Table 1.

Figure 1 displays optimal policy cost as a function of cycle time. The determination of the optimal

Figure 1 Best expected cost per unit time for a specified cycle time

policy required the linear program to be solved at each given expected cycle time followed a one-dimensional search to find the minimal cost. We speed up this one-dimensional search by using a simple golden-section search. (The results shown are for a grid with $x_j - x_{j-1} = 0.024$ for all j .) As can be seen from Figure 1, the optimal policy has an expected cycle length of 0.72. The actual policy is displayed graphically in Figure 2.

In Figure 2, the vertical axis contains the number of machines. The horizontal axis is the elapsed time since the beginning of a cycle and the shaded region is the region where group replacement should be made. From Figure 2, the optimal policy can be described as follows: at any time prior to 0.48, replace only if three or more machines are down; between times 0.48 and 0.9, replace if two or more machines are down; between times 0.9 and 1.2, replace if any machines are down; after 1.9, replace the system no matter how many machines have failed. This policy has an expected cost per unit time of 53.9. (The best (m, t) policy is $(3, 0.75)$: repair once three machines are down or 0.75 days have elapsed, with a cost of 56.04 (3.97% higher than optimal).) The best m policy is $m = 2$: repair once two machines are down with a cost of 58.71 (8.92% above optimal).

Table 1 System costs

Cost	Value
c_0	15
c_b	7
c_r	2
c_d	20

Continuous Observation

A more general problem is to allow the state space to be $\{(i, x): 0 \leq i \leq n, 0 \leq x < x_m\}$, where the assumption is that x_m is chosen so large that replacement must occur before x_m (the assumption of an increasing hazard rate implies that such an x_m exists).

Figure 2 Optimal maintenance policy

As before, the analysis will be for randomized strategies. An optimal solution, of course, will always turn out to be a nonrandomized strategy. In this context, a randomized strategy s is a function from $\{(i, x): 0 \leq i \leq n, 0 \leq x < x_m\}$ to the closed interval $[0, 1]$, with $s(i, x)$ being the probability that group replacement will be performed when the system is in state (i, x) . Let K^* denote $\inf_s \{K(s)\}$, where, as before, $K(s)$ denotes the expected cost per unit time associated with the policy s .

As in the section titled “Optimal Policies When System is Observed at a Fixed Number of Times”, let $0 = x_0 < x_1 < x_2 < \dots < x_m$ define a given set of times. The objective of this section is to demonstrate that the times x_j can be chosen so that a policy defined on this restricted space is arbitrarily close to K^* . Any policy defined on this restricted space is also a policy that can be applied in the continuous observation case and consequently, its expected cost per unit time is an upper bound on K^* . Theorem 3, which follows, shows how to obtain a lower bound for K^* .

Theorem 3 Let $0 = x_0 < x_1 < x_2 < \dots < x_m$ be a given set of times at which the system is observed. (So the state space is $\{(i, x_j): 0 \leq i \leq n, 1 \leq j \leq m\}$.) Suppose that δ^* is the policy on this space that minimizes the expected cost per unit time where transition costs are given by

$$c'_{ija} \equiv \begin{cases} c_{ij1} - ic_d(x_j - x_{j-1}) + (n-i)c_d & \\ \int_{x_{j-1}}^{x_j} F_{j-1}(x) dx - (c_b - c_r)(n-i) & \\ \{F_{j-1}(x_j) - F_{j-1}(x_{j-1})\} \text{ for } a = 1 & \\ c_{ij0} \text{ for } a = 0 & \end{cases} \quad (35)$$

and the c_{ija} are provided in equation (4). Then the expected cost per unit time for δ^* using the costs c'_{ija} is a lower bound for K^* .

Proof. Let s be any given strategy defined on the space $\{(i, x): 0 \leq i \leq n, 0 \leq x < x_m\}$. For the given partition $\{x_j\}$, let δ^s denote the strategy on the discrete space $\{(i, x_j): 0 \leq i \leq n, 0 \leq j \leq m\}$ be defined as follows: group replacement using strategy δ^s occurs at time x_j if and only if a decision maker who had been using s would have replaced the system at time $x \in (x_{j-1}, x_j]$; set $\delta^s(i, x_m) \equiv 1$ for all i .

The expected downtime cost over a cycle using δ^s is larger than that using s since replacement is being deferred. Suppose that, using δ^s , group replacement is required at (i, x_j) . Then, for this case, the extra downtime cost can be no more than

$$ic_d(x_j - x_{j-1}) + (n-i)c_d \int_{x_{j-1}}^{x_j} F_j(x) dx \quad (36)$$

where the first part of equation (36) is the downtime accrued by the i failed machines over the period from x_{j-1} to x_j and the second part of equation (36) is an upper bound for the expected downtime for extra machines that might have failed during $(x_{j-1}, x_j]$.

The expected replacement cost over a cycle using δ^s is larger than that using s since replacement is being deferred and extra replacement costs might be incurred – the extra cost increment incurred for each extra failed machine being $c_b - c_r$. Suppose that, using δ^s , group replacement is required at (i, x_j) , the conditional probability that a machine will fail between x_{j-1} and x_j equals $F_{j-1}(x_j) - F_{j-1}(x_{j-1})$. Thus, the expected extra replacement costs incurred by waiting to replace at x_j do not exceed

$$(c_b - c_r)(n-i)\{F_{j-1}(x_j) - F_{j-1}(x_{j-1})\} \quad (37)$$

The extra expected downtime cost incurred by using δ^s is no more than the amounts given in equations (36) and (37). So subtracting these amounts from the replacement cost on replacement, more than compensates for these amounts. So calculating the expected cost per unit time for δ^s using replacement costs of

$$\begin{aligned} & c_{ij1} - i c_d(x_j - x_{j-1}) + (n - i)(c_b - c_r) \\ & \times \int_{x_{j-1}}^{x_j} F_{j-1}(x) dx - (c_b - c_r)(n - i) \\ & \times \{F_{j-1}(x_j) - F_{j-1}(x_{j-1})\} \end{aligned} \quad (38)$$

instead of c_{ij1} will result in a lower value than the expected cost over the cycle using s .

The expected length of each renewal cycle is longer when using δ^s than s . This is because δ^s defers group replacement to the first time x_j that comes after the strategy s would have replaced the machines. If the policy s replaces at $x \in (x_{j-1}, x_j]$, then the length of the cycle using δ^s is no more than

$$x_j - x_{j-1} \quad (39)$$

units longer than if s were used.

From the above, the expected cost per unit time for δ^s , where the transition costs are given by the modified values c'_{ija} , is lower than the expected cost per unit time for s where this latter cost is computed using the (true) transition costs given by c_{ija} . This gives the required result since it holds true for any s .

From equations (36), (37) and (39), the difference between the expected cost per unit time for the case of a fixed partition and the value obtained from procedure in Theorem 3 goes to zero as $\max_j |x_j - x_{j-1}| \rightarrow 0$. In other words, the optimal policy for the state space $\{(i, x_j) : 0 \leq i \leq n, 1 \leq j \leq m\}$ can have an expected cost per unit time as close as desired to K^* by choosing a fine enough partition $\{x_j\}$.

Example Suppose there are six machines with i.i.d. $\gamma(\alpha = 5, \beta = 5)$ distributed failure times with costs as shown in Table 1. Table 2 contains the values of the objective function for different equally spaced partitions of the interval 0 to 3. As can be seen, even moderately sized partitions produced reasonable results.

Table 2 Results for varying partition step sizes $x_j - x_{j-1}$

Costs		
Partition step size	Partition size	Upper bound–lower bound
0.12	25	0.971
0.06	50	0.861
0.04	75	0.825
0.03	100	0.706
0.024	125	0.524

Table 3 Comparison of costs for optimal policy to m and (m, t) policies

Parameter		Policy costs		Cost increase over optimal		
α	β	Optimal	(m, t)	m	(m, t) (%)	m (%)
7	7	49.44	50.56	53.93	2.27	9.08
7	5	36.87	37.82	39.28	2.58	6.54
7	3	22.72	23.15	23.61	1.89	3.92
5	7	73.61	75.42	79.18	2.46	7.57
5	5	53.9	56.04	58.71	3.97	8.92
5	3	33.84	35.55	37.18	5.05	9.87
3	5	118.79	118.92	127.16	0.11	7.05
3	7	91.87	92.27	100.17	0.44	9.03
3	3	60.56	61.34	66.47	1.29	9.76

Example Again, suppose there are six machines with costs as shown in Table 1. A comparison of the optimal policy with the results of m -failure and (m, T) -policies for various gamma distributions is shown in Table 3.

Conclusion

This paper introduces a group replacement policy that takes account of the actual state of the system at each stage. This general approach cannot have a higher expected cost per unit time than the m -failure, T -age, or (m, T) policies and is a generalization of those policies. The general approach is no harder to implement than any of these policies and has the great advantage of being intuitively much more acceptable. The drawback of the procedure is that more computational effort is required to find good policies. The adaptive policy allows the production manager to efficiently use the information provided by failing machines. This will result in a reduction in the variability of costs among cycles.

Replacement Strategies

Definitions and Main Characteristics

Our daily lives involve the observation, use, construction, and destruction of many systems. We replace the light bulbs when they burn out, take our cars to the repair shop when the brakes need to be replaced or the oil is due to be changed. The situations requiring a *replacement* are usually connected to wear out, aging, deterioration, or failure of the item/system involved. In this presentation we will assume that all of these processes are random.

Definition: A replacement policy π is a decision making rule that defines the time and type of replacement of an item or a system such that an objective defined by the decision maker is optimized. The main characteristics of any replacement policy are:

Objective function – A common criteria in deciding when to perform a replacement is economically justified, that is a cost function (called *objective function*), $G(x)$, is optimized with respect to a set of parameters. Examples are the smallest average replacement cost per unit time or the total discounted cost. Alternative objectives are the maximum reliability, minimum net present cost, internal rate of return (IRR), or any general utility function defined by the decision maker.

Time of replacement – A replacement can be performed: as soon as the item fails (also known as corrective maintenance), before failure (preventive maintenance), or in a certain amount of time after failure. This will be one of the objective function's parameters, call it T . We will try to find the value of T that optimizes the objective function.

Type of replacement – The item can be replaced with a new one or with an old (used) one. This is another one of the objective function parameters, denote it by a . As before, we would like to find the age of the system with which we will replace the “old” one that optimizes the objective function.

Failure time – The failure occurrences are assumed to be random following a general counting stochastic process $\{N(t), t \geq 0\}$, see Rausand and Høyland [1, p. 231]. The “failure time” will be the time between two consecutive failures.

We can formulate the general stochastic optimization problem of finding the optimal replacement policy $\pi = (T^*, a^*)$ as

$$\min_{T, a \in R^+} E[G(T, a, t)] \quad (1)$$

where E stands for the expectation operator taken with respect to a filtration up to time t defined by the counting process $N(t)$. The decision variables are T – time of replacement and a – age of the replacing item. Note that if we want to find the maximum of the objective function, it will be equivalent to finding the minimum of its negative value.

Here are some common replacement policies one can obtain for specific values of the time of replacement, T :

- Age replacement policy: the item/system is replaced upon failure or at age Y , whichever comes first (see **Multivariate Age and Multivariate Renewal Replacement**).
- Block replacement: the item/system is replaced at regular time intervals $X, 2X, \dots$ regardless of age (see **Block Replacement**).
- Group replacement: a group of items is replaced at the same time to take advantage of economies of scale (see **Group Maintenance Policies**).
- Condition-based replacement: a collection of variables measuring the state of system's **degradation** is monitored and replacement decision is made based on their values (see **Degradation Models**).
- Opportunity-based replacement: the replacement is performed at a time when *opportunity* arrives. Examples of opportunities are: scheduled downtime, lunch breaks, failure of a system in close proximity to the item of interest. The arrival process of the opportunities is assumed to be random.

There are three main replacement types based on the values of a :

- The failed item/system is replaced with a brand new one with age 0. This type of replacement is called *as good as new* or also known as **preventive maintenance**.
- $a = a_t$, where t is the time since last replacement and a_t is the age of the failed item. This replacement is called *as good as old*, or **minimal repair** (see **General Minimal Repair Models**).

- The age of the replacing item is different from 0 or the age of the failed item. This is called *imperfect repair* (see **Imperfect Repair; Multivariate Imperfect Repair Models**).

The literature on replacement policies is enormous. The earlier work was done in the early 1960s by Barlow and Proschan [2]. An excellent survey of the literature is presented by Florez and Feldman [3] and Dekker [4]. Rausand and Høyland [1] is one of the contemporary textbooks on reliability. Marquez and Heguedas [5] present a review of the recent research on **maintenance policies** and solve the problem of periodic replacement in the context of a semi-Markov decision processes methodology. We will review some of the most recent work on replacement policies and refer the readers to the above references for earlier research.

The reliability literature on replacement models and policies that allow for a change of the future failure behavior of the system is limited. There are several papers that could be classified as either models where replacement actions reduce the rate of failures or models where the replacement action reduces the (virtual) age of the system, see Rausand and Høyland [1, p. 287], for details.

Such problems where the replacement decisions may influence the future stochastic nature of the system are referred to as *decision-dependent-randomness* problems. For a general overview of the existing literature that relates to this class of problems see Morton and Popova [6]. Models with decision-dependent uncertainty are discussed by Jonsbråten [7] and Jonsbråten and Woodruff [8].

Lai *et al.* [9] analyze a single-unit system subjected to external shocks. The unit can fail due to aging or shock. This is an example where the failure rate of the system increases after a lethal shock or with aging. The policy is to replace the system after the n th shock or failure, whichever occurs first. They minimize the long-run expected cost per unit time to obtain the optimal value of n . Lai and Tang [10] consider a two-unit system where the failure of each unit either increases the failure rate of the other or brings it to an instantaneous failure. The system is replaced at age T or at failure, whichever occurs first. The value of T is obtained by minimizing the long-run expected cost per unit time.

Time Horizon and Objective Functions

An important characteristic of the replacement decisions is the time horizon over which we want to solve the optimization problem – it can be either finite or infinite.

Infinite Time Horizon

In the infinite case one can use existing limit theorems (for example from renewal theory and Markov decision process) to obtain the structure of the optimal replacement policy, see Ross [11] (see **Maintenance and Markov Decision Models; Markov Renewal Processes in Reliability Modeling**). The long-run expected cost per unit time and the total discounted cost are the two common objective functions used in this case.

Juang and Sheu [12] analyze a k -out-of- n system and find the optimal age replacement policy (see **Total Time on Test Plots**). They consider two approaches – one that minimizes the long-run cost per unit time, and a graphical approach based on the **total time on test** concept. Jiang and Ji [13] consider the age replacement policy by introducing a different objective – multiple attribute utility. In addition to cost they include the availability, reliability, and lifetime as attributes of the objective function.

The optimal replacement of an item under warranty is an important problem both for the manufacturer and the user. Iskandar and Sandoh [14] consider a system with a warranty period $[0, S]$ where opportunities for replacement occur according to a **Poisson process**. The policy is as follows: when the system fails at age $x \leq S$, a minimal repair is performed, if an opportunity occurs at age $S < x < T$, the system is replaced with probability p , and it is also replaced at age T . The optimal values of the parameters are obtained by minimizing the long-run expected cost. Iskandar and Murthy [15] study a combination of repair and replace strategies for a system under warranty. They obtain the optimal policy by minimizing the expected cost of servicing the warranty (see **Warranty Servicing**).

Finite Time Horizon

The finite time horizon is a bit more challenging since there are no existing general results from the stochastic/reliability literature to indicate which replacement

policy is optimal. Su and Chang [16] find the periodic maintenance policies that minimize the life-cycle cost over a predefined finite horizon. Galenko *et al.* [17] solve the combination of preventive replacement and minimal repair policies over a finite horizon by minimizing the total replacement cost where the time of replacement is an integer variable.

There are other objective functions used in the finite time horizon case. Net present value (NPV) is the difference between the sum of present values of the project's (replacement policy) future cash flows (computed as the difference between inflows and costs) and the initial cost of the project. The NPV approach is the most common method used in capital budgeting (since the decision when and how to replace fits within the capital budgeting framework).

When making the replacement decision, one chooses the option with the highest NPV. This simple rule does not work very well when the replacement decision involves choosing between two machines with unequal lives. Suppose that both machines can do the same job, but they have different operating costs and will last for different time periods. A simple application of the NPV rule suggests taking the machine whose costs have the lower present value. This choice might be suboptimal because the lower-cost machine may need to be replaced before the other one. The easiest way to compare the two machines involves calculating something called the *equivalent annual cost* of each machine. In other words, the NPV of the costs computed over the finite time horizon is converted into an annuity cost assuming that the machines will have to be part of the production process forever, that is into infinite horizon case. Examples of such necessities can be found in the health care system where a new admitting system may be needed every 5 years; making a decision about copy machines, replacing computers, and so on.

Another frequently used approach is the Internal Rate of Return, IRR. The basic rationale behind the IRR method is that it provides a single number summarizing the merits of a project. That number does not depend on the interest rate prevailing in the capital markets. The IRR is the discount rate that equates the NPV of the project to zero. The general decision rule is very simple: accept the project if the IRR is greater than the discount rate; reject the project if IRR is less than the discount rate. One very common cited difficulty is when this approach is

used to choose between mutually exclusive projects, which might be the case in the replacement policy framework. The problem arises since the IRR method ignores issues of scale. In other words, one project may have a higher IRR but its NPV may be low compared to the other project that has lower IRR but higher NPV. This is a very important issue in capital budgeting since the main objective of every company is to increase the shareholder's value (i.e., the value of the firm). Making a decision to choose between mutually exclusive projects by accepting the one with the highest IRR may not be the **optimal decision** from the point of view of maximizing the firm value. There are several ways in which one can solve this problem. One is to use the NPV method and make a decision based on highest NPV. Another way is to compute the incremental NPV and accept if it is greater than zero. A third one is to compare the incremental IRR to the discount rate and accept if the IRR is greater than the discount rate.

Some companies use the profitability index (PI) method to evaluate projects. It is the ratio of the present value of the future expected cash flows after initial investment divided by the amount of the initial investment. This approach shares the same advantages and disadvantages with the IRR rule. For mutually exclusive projects it ignores the issue of scale. Incremental cash flows have to be constructed and then the PI rule can be used. The project will be accepted if $PI > 1$. This rule is also useful in the capital rationing context. Suppose that the firm does not have enough capital to fund all positive NPV projects. In the case of limited funds, we cannot rank projects according to their NPVs. Instead, we should rank them according to PI. The PI measures the dollar return for the dollar invested, that is "the bang for the buck", and is useful for capital rationing. We should note that the PI does not work if funds are also limited beyond the initial time period and it is not useful over multiple time periods.

Both objectives, IRR and PI, can be applied to the replacement problem in the following situation. Suppose we have to compare an existing replacement policy to a "proposed" one (claimed to be economically better). Then we can compute the cost savings when the new policy is used, and construct both the IRR and PI objectives.

The above methods briefly describe some of the most commonly used approaches by companies. For additional examples and more detailed explanation

4 Replacement Strategies

see Ross *et al.* [18]. In reality, in addition to these methods companies use methods like payback, discounted payback, and accounting rate of return. The use of the methods varies with the industry. For example, firms that are better able to estimate cash flows are more likely to use NPV. Companies in the oil business or in energy-related businesses can do such **estimation**. But companies in the entertainment business, like motion-picture production may not be able to produce reliable cash flow estimates.

Failure Time

An important input to the optimization problem given in equation (1) is the failure time distribution, which measures the time between two consecutive failures. The exponential distribution is a common assumption, which implies that the system's failure rate function is constant over time. In this situation, preventive replacement will not be optimal and one needs to consider replacement only at failure.

It is also important to recognize the implications of the type of replacement to the future failure time distribution. The replacement with a new item corresponds to having independent and identically distributed (i.i.d.) times between failures. This scenario is the best one if we have to estimate the failure time distribution's parameters from a data set since standard statistical techniques will be applicable.

The replacement with an old item has a variety of options: the age of the "new" item is the same as the age of the item that it is replacing, or it can be different. The first case is referred to as "replacement with as good as old" (or minimal repair) and the resulting stochastic failure process is the nonhomogeneous Poisson process, see Brown and Proschan [19].

Recently, several papers analyzed a system in which failure and repair times follow a geometric process. Zhang *et al.* [20] consider a deteriorating system and find the optimal replacement time. They investigate two replacement policies: one based on the accumulated working time T of the system, and the other based on the accumulated number N of failures. The optimal values of T and N are obtained by minimizing the long-run expected cost per unit time. Zhang [21] studies a deteriorating system and obtains the optimal replacement policy based on the number of failures by minimizing the long run expected cost per unit time.

Hu and Yue [22] model a deteriorating system (according to semi-Markov process) that operates in semi-Markov environment. They show the existence of an optimal control limit policy that minimizes the discounted total cost over finite and infinite time horizon. Moustafa *et al.* [23] analyze a system that deteriorates according to a multistate semi-Markov process. They obtain a control limit policy using the policy-iteration algorithm for the expected long-run cost rate of the system. Chen and Feldman [24] formulate a Markov decision process model for a deteriorating system and show that the control limit policy for a modified repair/replacement is optimal over the space of all possible policies under the discounted cost criterion.

A different failure time model is presented by Castro and Alfa [25], who model a single-unit system with operational time according to a phase-type distribution. In addition the system is subjected to external failures that arrive as a Bernoulli process. They present two versions of the age replacement policy. Archibald *et al.* [26] use Cox regression model to estimate the underlying maintenance behavior. They develop a stochastic dynamic programming approach to obtain the optimal replacement policy for a system subject to a decay. In addition they investigate the stability of the results to changes in the cost parameters.

Castanier *et al.* [27] propose a combined replacement policy (based on periodic and aperiodic inspections) for a stochastically deteriorating system. They model the deterioration process as a gamma process (see **Warranty: Usage and Wear Process for**) and derive the long-run expected cost per unit time for this policy. Barros *et al.* [28] focus on a parallel system of two units with dependent failures and subject to external shocks that arrive according to a Poisson process (see **Poisson Processes**). The failures, however, are detected with a given probability. The replacement policy is a group replacement, that is both items are replaced regardless of which one has failed. The objective function is the long-run expected cost per unit time.

A different approach to failure times modeling is via the Bayesian perspective. The classical failure time modeling assumes a parametric distribution (like exponential or Weibull) with parameter values that are, for instance, the maximum-likelihood estimates. Standard Bayesian modeling assumes a parametric lifetime distribution and makes inferences about its parameters via the posterior distribution

derived using Bayes' theorem, see Bernardo and Smith [29]. A review of the Bayesian approaches to maintenance intervention is presented in Wilson and Popova [30]. Chen and Popova [31] propose two types of Bayesian policies that learn from the failure history and adapt the next maintenance point accordingly. They find that the optimal time to observe the system depends on the underlying failure distribution. A combination of **Monte Carlo simulation** and optimization methodologies is used to obtain the problem's solution. Another related reference is Mazzuchi and Soyer [32]. In Popova [33], the optimal structure of Bayesian group-replacement policies for a parallel system of n items with exponential failure times and random failure parameter is presented. The paper shows that it is optimal to observe the system only at failure times. For the case of two items operating in parallel the exact form of the optimal policy is derived.

A more general approach is to use nonparametric Bayesian approach which, for instance, takes the hazard rate of the failure time to be a random "parameter", and puts the continuum of all distributions as its prior. This notion of placing a prior on function spaces is termed *nonparametrics*. Ferguson [34] was the first to consider this idea from a Bayesian perspective. Since then, there have been hundreds of papers in a variety of contexts that use Bayesian nonparametric models, see Dey and Rao [35]. Once a prior has been put on the space of hazard rates, the posterior distribution of the hazard rate process is derived. Typically, this posterior distribution will not have a closed form solution. **Markov chain Monte Carlo** (MCMC) methods are used to obtain inferences from the posterior distributions of interest; see, for example, Krishnan *et al.* [36]. Merrick *et al.* [37] discuss optimal **replacement strategies** for machine tools when their failure behavior is modeled via a Bayesian semiparametric proportional hazards model. The problem of a finite horizon, single-item maintenance optimization structured as a combination of preventive and corrective maintenance in a nuclear power plant environment is analyzed by Damien *et al.* [38]. In addition they present Bayesian semiparametric models to estimate the failure time distribution and costs involved.

A real-world application of replacement strategies is presented by Brezavscek and Hudoklin [39], who develop a block-replacement and spare-provision policies for the electric locomotives in Slovenian

Railways. Aka *et al.* [40] investigate the relationship between a replacement and inventory policy for a manufacturing system.

Imperfect Repair

Introduction

When a system fails, one has a choice of replacing it with a brand new system or repairing it. When a system is replaced with a brand new system, the lifetime of the replaced system has the same distribution F as the original system. What will be the distribution of the lifetime of a repaired system? The term *imperfect repair* is used both to describe the nature of the repair and the distribution of the lifetime of the repaired system and comes in many flavors. In fact, replacement by a brand new system itself can be called a *perfect repair*. Ascher [1] introduced the concept of *minimal repair* in which the repaired system has the same distribution as a working new system with the age of the recently failed system. In symbols, the survival function of the minimally repaired system is given by $\bar{F}_t$, where

$$\bar{F}_t(s) = \frac{1 - F(s+t)}{1 - F(t)}, \quad s > 0 \quad (1)$$

and t denotes the time of the previous failure.

Let $\{S_j\}$ denote the failure times of the system maintained by repairs and let $\{T_j\}$ the interfailure times, where $T_j = S_j - S_{j-1}$ and $S_0 \stackrel{\text{def}}{=} 0$. A stochastic model for repairs of such a system (also called a *repair model*) should specify the joint distribution of $\{T_1, T_2, \dots\}$.

Note that F is the distribution of T_1 , the time of first failure of the system. Under a *perfect repair model*, $\{T_1, T_2, \dots\}$ are independent and identically distributed according to F . Again, $P(T_2 > s | T_1 = t) = F_t(s)$ when a minimal repair is performed after the first failure. More generally, $P(T_{n+1} > s | A_n = t) = \bar{F}_t(s)$, where A_n is the effective age of the system following the first n failures and repairs. Brown and Proschan (BP) [2] describe another repair model by stipulating that, following any system failure, a perfect repair or a minimal repair is made with probability p and $1 - p$, respectively where p is in $[0, 1]$. This will allow one to write down the joint distribution of $\{T_1, T_2, \dots\}$ to completely define the *imperfect repair model*. This will be called the BP repair model. Another repair model was introduced by Block, Borges, and Savits [3] (BBS). In this model, the p of the BP model is generalized to

be a function of time t and upon the n th failure a perfect repair is made with probability $p(A_n)$ and a minimal repair otherwise, where A_n is the age of the system calculated from the beginning or from the last full repair, whichever came later. More properties of these repair models are described in the section titled “Repair Models”.

There have been several other repair models described in the literature including the Dorado, Hollander, and Sethuraman (DHS) [4] model, the Kijima [5] models, and the Last and Szekli [6] model. The DHS model is more fully described in **Nonparametric Methods for Analysis of Repair Data**.

A common inference problem in repair models is the **estimation** of F . This will allow the estimation of other features of the repair model. In the section entitled “Inference in Repair Models”, we describe the nonparametric maximum-likelihood estimator (NPMLE) of F derived by Whitaker and Samaniego (WS) [7]. Hollander *et al.* [8] (HPS) used counting processes to find more properties of the WS estimator. This is described in the section titled “Inference using Counting Processes”. The estimation of F in the DHS model is described in **Nonparametric Methods for Analysis of Repair Data**. The section titled “Other Inference Studies on Imperfect Repair” considers additional inferential methods for imperfect repair.

Repair Models

The BP and BBS models discussed in the section titled “Introduction” involve the basic notions of *perfect repair*, which restores a repairable system, upon failure, to its condition when new and *minimal repair*, which restores a failed system to its condition just prior to failure. When a *perfect repair* is performed, the repaired system has the lifetime distribution F of a new system. When a *minimal repair* is made, the repaired system has the distribution of the residual lifetime of a system of age t , where t is the failure time of the system that is, the survival function is given by $\bar{F}_t(s)$ defined in equation (1). BP and BBS introduce a stochastic mechanism for determining whether a given repair will be perfect or minimal.

The BP model for imperfect repair simply stipulated that, following any system failure, a perfect

2 Imperfect Repair

repair was made with probability $p \in [0, 1]$, with a minimal repair being made otherwise. Under this modeling assumption, BP showed that the distribution of the time Y until the first perfect repair is $\bar{F}_Y(t) = (\bar{F}(t))^p$, where $\bar{F} = 1 - F$ is the survival function of the system when new. BP noted the interesting fact that the model implied the proportional hazard property for Y , (i.e., $R_Y(t) = pR(t)$ for Y , where $R = -\ln(\bar{F})$ is the hazard function of the system when new), obtaining this property as a derived result rather than as an initial assumption. Proschan, well-known for his sense of humor, liked to say that this property was evidence that “among the various ways one might model imperfect repair, God favored this particular formulation”. A number of preservation properties for the model were established in BP, including results such as: if F belongs to the IFR, DFR, IFRA, DFRA, NBU, or NWU classes, the distribution F_Y belongs to the same class. The paper also proved several monotonicity results, including (a) $E(Y)$ is an increasing (decreasing) function of the model parameter p when F belongs to the NBUE (NWUE) class and (b) $N(t)$, the number of failures in the interval $[0, t]$ is stochastically decreasing (increasing) in p when F is NBU (NWU). The paper is generally considered the seminal contribution on “imperfect repair”.

The BBS model, which generalizes the BP model, allows the probability of a perfect repair following any given failure of the system to depend on the age t at which the system failed; this probability is thus represented by a function $p(t)$ taking values in $[0, 1]$ for $t > 0$. While the model is well defined for any choice of such a function $p(\cdot)$, the paper shows that the time Y until a perfect repair is finite with probability 1 if and only if

$$\int_0^\infty p(t) dR(t) = \infty \quad (2)$$

In this case, assuming for simplicity that F is absolutely continuous, the distribution F_Y of Y is given by

$$F_Y(t) = 1 - \exp \left\{ - \int_0^t \frac{p(s)}{(1 - F(s))} dF(s) \right\} \quad (3)$$

and has failure rate $r_Y(t) = p(t)r(t)$, where $r(t)$ is the failure rate of F . The intuition that $p(t)$

might well be a nondecreasing function in any real application, making a perfect repair more likely as the system grows older, is well accommodated by the BBS model. While monotonicity of p is not required in general, several results are derived for this important special case. BBS also identify the successive times until complete repair as a specific renewal process. When $p(t)$ is increasing (decreasing), BBS prove that F_Y is IFR, IFRA, NBU or DMRL (DFR, DFRA, NWU or IMRL) when F belongs to the same class. The paper also contains some monotonicity properties of the model and provides an example showing that F_Y need not be NBUE when F belongs to the NBUE class.

A number of subsequent papers have generalized the BP or the BBS model in a variety of ways. Notable among these are the multivariate generalizations studied by Shaked and Shantikumar [9] Savits [10] Sheu and Griffith [11, 12] and Hu [13]. Several papers have shed light on various forms of stochastic ordering between or among random variables obtained *via* the BP or the BBS model. Contributions in this direction may be found in Hu [13], Last and Szekli [6] and Belzunce and Shaked [14]. Papers that study imperfect repair models in special contexts include Finkelstein [15], where these models are examined for systems subject to shocks, Biswas and Sarkar [16], where imperfect repair is studied with maintainability and availability issues in mind, and Li and Shaked [17], where **preventive maintenance** strategies are studied within an imperfect repair framework.

Inference in Repair Models

The first published treatment of problems of nonparametric statistical inference for imperfect repair models is that of WS. These authors addressed the problem of estimating the unknown parameters (p, F) of the BP model and $(p(\cdot), F)$ of the BBS model. HPS, using different techniques, provide a broader asymptotic analysis of the WS estimator, while Presnell *et al.* [18] (PHS) examine the question of testing the “minimal repair” assumption of the BP and BBS models. These papers have been followed by a number of inference papers on imperfect repair. The sections titled “Inferences using Counting Processes” and “Other Inference Studies on Imperfect Repair” discuss several such papers with a view toward

providing the reader with a sense of the scope of generalizations and alternative approaches contained in the statistical literature on imperfect repair models.

WS took a NPMLE approach to estimation in the BP and BBS models. They demonstrate that the BP and BBS models are not identifiable on the basis of observed interfailure times alone and that data on the mode of repair after each observed failure would need to be observed (or imputed in some justifiable fashion) in order to estimate p and F using classical statistical methods. WS assume that, under inverse sampling until the occurrence of the m th perfect repair, data of the form $\{(t_i, z_i), i = 1, 2, \dots, n\}$ is available, where t_i is the age of the system at the time of the i th failure and $z_i = 1$ if the i th repair is perfect and $z_i = 0$ otherwise. Under this assumption, WS show that the NPMLE is well defined only when $z_{(n-1)} = 1$, where $z_{(n-1)}$ is the value of z corresponding to the second oldest age of failure. Under the BP model, WS show that the pair of estimators $\hat{F}(t) = 1 - \prod_{j=1}^i k_j / (k_j + 1)$ for $x_{(i)} \leq t < x_{(i+1)}$, where $k_i = \sum_{j=1}^i z(j)$, and $\hat{p} = m/n$ to be the NPMLE when it exists and to be a “neighborhood NPMLE” with respect to the sup norm in general. WS then prove the weak convergence of the process $\sqrt{m}(\hat{F}(t) - F(t))$ to a zero-mean Gaussian process on any fixed interval $[0, T]$ with $F(T) < 1$, and show that $\hat{F}$ has a smaller asymptotic variance than two natural alternative estimators of F . Extensions to estimation for the BBS model and to inference in renewal testing are also discussed.

Inference using Counting Processes

Using counting process techniques, HPS extended the large sample theorems of WS to the whole line. HPS also derived a nonparametric asymptotic simultaneous confidence band for F . HPS assumed

$$F(\tau_F) = 1, \int_{(0, \tau_F)} p(t) \frac{dF(t)}{\bar{F}(t-)} = \infty \quad (4)$$

where $\tau_F = \inf\{t \in [0, \infty] : F(t) = 1\}$. They considered the situation where one observes n independent copies of the BBS process, each until the time of its first perfect repair. Let T be the first failure age at which only one item is at risk. Let $X_{(k)}$ denote the ordered values of the observed failure ages of

the n BBS processes. The WS estimator can be written as

$$\hat{\bar{F}} = \prod_{X_{(k)} \leq t \wedge T} \left(1 - \frac{1}{Y(X_{(k)})}\right) \quad (5)$$

where $Y(X_{(k)})$ is the number of processes still being observed just prior to $X_{(k)}$.

Because the BP and BBS models are based on an assumption that imperfect repairs are indeed minimal repairs, it is useful to test that assumption. Presnell *et al.* [18] constructed two asymptotically distribution-free tests of the minimal repair assumption in the BBS model. Let $\hat{\bar{F}}_e$ denote the empirical survival function based on the initial failure times of the systems of the systems being observed. PHS developed a Kolmogorov–Smirnov test based on the maximum absolute difference between $\hat{\bar{F}}_e$ and $\hat{\bar{F}}$, the WS estimator. PHS also developed a Wilcoxon-type test based on $\int_0^\infty \hat{\bar{F}}_e d\hat{\bar{F}}$ (see **Nonparametric Methods for Analysis of Repair Data**).

Other Inference Studies on Imperfect Repair

Among the subsequent inferential studies involving imperfect repair, several papers provide analytical treatments in substantially new settings – either by considering different **sampling schemes**, by placing additional constraints on the underlying model or by taking a different inferential approach. Examples of such papers include the following. Lim [19] considers the estimation of the underlying distribution F in the BP model using masked data; the case when F is Weibull is given special attention. Sethuraman and Hollander [20, 21] introduced a new class of Partition Based priors and showed that it is a conjugate class for a large class of general repair models that includes the BBS model. They used this class and a subclass called Partition Based Dirichlet priors, which also forms a conjugate family, to develop Bayesian nonparametric estimators for repair models, including a Bayesian nonparametric competitor of the WS estimator. Baker [22] proposed data-based modeling of the failure rate in an imperfect repair setting. Kvam *et al.* [23] derived the NPMLE $\hat{r}(t)$ of the failure rate of a system subject to imperfect repair and the additional condition that the system’s lifetime distribution belongs to the IFR class. They established

the strong consistency of $\hat{r}(t)$ in an interval $[a, b]$ under the assumption that the true failure rate $r(t)$ is continuous and increasing in that interval.

Load-Sharing Models

Introduction

Consider a system of components whose lifetimes are governed by a probability distribution. *Load sharing* refers to a model of stochastic interdependency between components that operate within a system. If components are set up in a parallel system (*see Parallel, Series, and Series-Parallel Systems*) for example, the system survives as long as at least one component is operating. In a typical load-sharing system, once a component fails, the remaining components suffer an increase in failure rate due to the extra “load” they must encumber due to the failed component.

Component interdependencies are discussed in **Dependence; Aging and Positive Dependence; Measures of Association**. Another model for component interdependency is called a *shock model*, such as Marshall and Olkin [1] bivariate exponential model, which enables the user to model stochastic dependencies between component lifetimes by incorporating latent variables to allow simultaneous component failures. For example, suppose two components in a system are characterized by failure processes Λ_1 and Λ_2 . In a shock model, we can add a new process Λ_3 that characterizes events causing both components to fail, hence the overall failure process for the components become $\Lambda_1 + \Lambda_3$ and $\Lambda_2 + \Lambda_3$. This is the basis for most dependent failure models in probabilistic risk assessment, including *Common Cause Failure* models used in the nuclear industry; see Chapter 8 of Bedford and Cooke [2].

In contrast to the shock model, the load sharing creates a *dynamic* reliability model in which component lifetime distributions may or may not change throughout the course of a system lifetime. Daniels [3] originally adopted the load-share model to describe how the strain on yarn fibers increases as individual fibers within a bundle break. In this case, reliability is measured from strength instead of time until failure. Freund [4] formalized the **probability theory** for a bivariate exponential load-share model.

In general, the shock model provides an easier avenue for multivariate modeling of system component lifetimes. However, dynamic models such as the load-share model are deemed more realistic in environments where a component’s performance can

change once another component in the system fails or degrades. In typical applications of the load-share model, the group of operating components share a load (e.g., current, stress, weight) and once a component within the system fails, the failure rate of the surviving components increase because there are fewer components to share the constant load.

The load-sharing framework can apply to general problems of detecting members of a finite population. If resources allocated for finding a finite set of items are defined globally, rather than assigned individually, then once items are detected, resources can be redistributed for the problem of detecting the remaining items. This action gives rise to a load-sharing model. For bridge construction, some beams connected to the girder are further supported by a set of welded joints. The failure of one or two welded joints can cause the increase of stress on the remaining joints, inducing a load-share model.

Load-Share Rules

Perhaps the most important element of the load-share model is the rule that governs how failure rates change after some components in the system fail. This rule depends on the reliability application and how the components within the system interact that is, through the structure function. For example, an *equal load-sharing* rule, illustrated in Figure 1, implies that the extra load caused by the failed component is shared equally among the surviving ones. A *local*

Figure 1 Illustrative load transfer with an equal load-sharing rule

2 Load-Sharing Models

Figure 2 Illustrative load transfer with an local load-sharing rule, where the load from a failed component is transferred to its closest neighbors

load-sharing rule, illustrated in Figure 2, dictates that a failed component's load is transferred to adjacent components; the proportion of the load the surviving components inherit depends on their distance to the failed component.

More generally, a *monotone load-sharing* rule states that the load on the surviving components is nondecreasing with respect to the failure of other components in the system. Not all load-share rules need to be monotone. In finite population sampling, the event of finding one of the n observations might decrease the rate for finding the others. To model the detection rate in software debugging for example, the detection time for existing faults can depend on the number of other faults in the software that have already been found (*see Software Reliability Modeling and Analysis*). The discovery of a critical fault in the software might help reveal or conceal other yet undetected bugs. If other faults are more concealed, they have a decreased rate of discovery in the debugging process.

For assessing an unknown load-sharing rule, Kim and Kvam [5] model the dynamic nature of **component reliability** through proportional hazards. The baseline component failure time distribution is denoted by F . The hazard function (or cumulative hazard rate) corresponding to F is $R(x) = -\log(1 - F(x))$, and the hazard rate is $r(x) = f(x)[1 - F(x)]^{-1}$, where $f(x)$ is the density of F . Until the first component failure, the failure rate of each of k components in the system equals the baseline rate

$r(x)$. Upon the first failure within a system, the failure rates of the $k - 1$ remaining components jump to $\gamma_1 r(x)$, and remain at that rate until the next component failure. After this failure, the failure rates of the $k - 2$ surviving components jump to $\gamma_2 r(x)$, and so on. The failure rate of the last remaining component is $\gamma_{k-1} r(x)$. An equal load-share rule is implied by the $k - 1$ parameters $\gamma_1, \gamma_2, \dots, \gamma_{k-1}$.

To illustrate the relationship of the load-share rule to the system failure process, we consider Daniels' original application for modeling fiber strength.

Stress-Strength Models

For researchers in the textile industry who investigate the reliability of composite materials, a bundle of fibers can be considered as a parallel system subject to a steady tensile load. The rate of failure for individual fibers depends on how the unbroken fibers within the bundle share the load of this overall stress. The load-share rule of such a system depends on the physical properties of the fiber composite. Yarn bundles or untwisted cables tend to spread the stress load uniformly after individual failures. This leads to an equal load-share rule, which implies the existence of a constant system load that is distributed equally among the working components.

In more complex settings, a bonding matrix joins the individual fibers as a composite material, and an individual fiber failure affects the load of certain surviving fibers (e.g., neighbors) more than others, dictated by a local load-sharing rule. If individual fiber strengths are independently and identically distributed with distribution function F , the (parallel) system strength is

$$Y_n = \max_n \left\{ \frac{n - k + 1}{n} X_{k:n}, k = 1, \dots, n \right\} \quad (1)$$

Unfortunately, the distribution F_{Y_n} for Y_n becomes intractable quickly as n increases. Suh *et al.* [6] developed a recursive formula for F_n

$$F_{Y_n} = \sum_{i=1}^n \binom{n}{i} (-1)^{i+1} (F(x))^i F_{n-i} \left(\frac{nx}{n-i} \right) \quad (2)$$

that allows algorithmic computation, but even this solution becomes computationally infeasible with large n .

As an alternative approach, consider a system with each fiber undergoing a positive stress level x . As

x increases, more and more individual fibers break. In this scenario, however, the system load actually decreases at the instance of failure because here the system load is measured as the total stress divided by the number of surviving fibers. Now the actual load in the system (per fiber) at stress level x is

$$L(x) = xn^{-1} \sum_{i=1}^n I(X_i > x) \quad (3)$$

Because $x^{-1}nL(x)$ is binomially distributed, $L(x)$ has an asymptotic normal distribution with mean $x(1 - F(x))$ and variance $x^2F(x)(1 - F(x))$. The mean is unimodal in x , so there is a stress value x_0 such that $L(x_0)$ represents the maximum load the system can endure. For example, if $F(x) = x$, $0 \leq x \leq 1$ (strength is uniformly distributed between 0 and 1) then $x_0 = 0.5$, the maximum value of $x(1 - x)$.

Various techniques have been used to approximate $P_n(x) = n^{-1} \sum I(X_i \leq x)$ in $L(x) = x(1 - P_n(x))$. These are summarized in Crowder *et al.* [7]; Barbour [8] approximation shows a slight improvement over the others based on $P_n(x) \approx \Phi(z_x)$, where

$$z_x = \frac{\sqrt{n}(x - L_0 - \lambda \Delta^{1/3} n^{-2/3})}{\sigma^2 + \gamma n^{-1/2} \Delta^{2/3}} \quad (4)$$

$L_0 = L(x_0)$, $\sigma^2 = x_0^2 F(x_0)(1 - F(x_0))$, and

$$\Delta = \frac{x_0^4 F'(x_0)^2}{2F'(x_0) + x_0 F''(x_0)} \quad (5)$$

(λ, γ) are constant with $\gamma \approx -0.317$ and $\lambda \approx 0.996$. McCartney and Smith [9] carefully evaluated several approximation techniques, noting that the Barbour technique outperform other methods in the lower tail of the distribution.

Time-to-Failure Models

The load-share model has found broad application in life testing and dependent systems analysis since first being developed for material strength models. In most examples, load-sharing models serve as a detriment to systems, especially **parallel systems**. Most research has emphasized parametric lifetime distributions for the dependent components (e.g., Exponential, Weibull) with an assigned load-sharing rule to characterize the dependence. Rydeñ [10] extended the load-sharing framework to nonparametric **estimation** of component and

system lifetime using the same load-sharing rules of Daniels [3].

As a simple example, if the components of a parallel system have independent exponential distributions with failure rate λ , it is easy to show through spacings (the time between successive failures in the system) that the expected system lifetime is $\binom{n+1}{2} \lambda^{-1}$. However, if there is a load-sharing system in which the load of the failed component is added to the other components, the expected system lifetime is reduced to λ^{-1} . This is another consequence of the memoryless property that is, for $0 < a < t$, if $X \sim \text{Exp}(\lambda)$, $P(X > t | X > a) = P(X > t - a)$. In this case, it does not even matter if the load is shared equally by all the surviving components or whether the load is put only on one or two survivors.

Figure 3 shows the expected lifetime for parallel system of Weibull(a, b)-lifetime components. The scale parameter (a) equals one and the shape parameter (b) changes from one to five, so the left-most case refers to the exponential model, where the expected lifetime is 1.0. For the components, the failure rate is $r(t) = t^b$. Here, the load from a failed component is assumed to be distributed equally among the surviving components *via* the scale parameter as described by Kvam and Peña [11] and Liu [12].

With complex load-sharing rules, the number of parameters can escalate dramatically. Lynch [13] showed that complex systems of Weibull-distributed components, in a load-sharing model, can be modeled using a mixture of gamma-type distributions.

Figure 3 Expected parallel system lifetime versus shape parameter of Weibull-distributed components. The shape parameter changes from 1 (Exponential case) to 5. Curves are for cases $n = 20$ (highest), $n = 10$ (middle) and $n = 5$ (lowest)

Estimating the Load-Sharing Rule

Using nonparametric **maximum likelihood estimation** (MLE), Kvam and Peña [11] estimated a simple load-sharing rule based on independent identically distributed (i.i.d). parallel systems for which the failure rates of all components were equal, but the change in rate after a component failure depends on the set of functioning components in the system. The proportional hazard model by Kim and Kvam [5] is applied to estimate the load-sharing rule; that is, failure rate changes are characterized by $k - 1$ unknown parameters $\gamma_1, \gamma_2, \dots, \gamma_{k-1}$ and the unknown baseline distribution or hazard function. In this case, estimating the underlying baseline functions F was of primary interest.

If X_{ij} represents the lifetime of the j th component in the i th parallel system, then the random spacing T_{ij} is the time between j th failure and $(j - 1)$ th failure for the i th system. Kim and Kvam [5] considered the exponential model. For this special case where $i = 1, \dots, n$ and $j = 1, \dots, k$, the likelihood function for the i th system is

$$L_i(\theta, \boldsymbol{\gamma}; t_{i1}, t_{i2}, \dots, t_{ik}) = k! \theta^k \prod_{j=1}^{k-1} \gamma_j \exp\left(-\theta \sum_{j=1}^k (k - j + 1) \gamma_{j-1} t_{ij}\right) \quad (6)$$

Although the likelihood provides no closed form solution to obtaining MLEs, a Gauss-Seidel algorithmic method can be used to solve them. Kim and Kvam [5] also considered order restricted inference caused by monotone load sharing where $1 \leq \gamma_1 \leq \gamma_2 \leq \dots \leq \gamma_{k-1}$. In this case, a component failure causes the increase in the work-load of the other components, which can equate to an increase of failure rate.

Kvam and Peña [11] generalized the special case of Kim and Kvam [5] in which the components are distributed exponential. $S_{i,1} < S_{i,2} < \dots$ represents the successive component failure times for the i th system. With the counting processes

$$N_i(t) = \sum_{j=1}^k I(S_{i,j} \leq t), \quad i = 1, 2, \dots, n \quad (7)$$

$N_i(t)$ represents the number of component failures for the i th system that occurred by time t . We can express γ in terms of the counting processes

as $\gamma[N_i(w)] = \sum_{j=0}^{k-1} \gamma_j I(N_i(w) = j)$. To formulate the nonparametric likelihood in terms of stochastic processes, let

$$Y_i(w) = (k - N_i(w-)) I(\tau \geq w) \quad (8)$$

Define $\mathcal{F}_{it} = \sigma\{(N_i(w), Y_i(w+)); w \leq t\}$ to be the filtration generated by the i th system up to time t , and let $\mathcal{F}_t = \bigvee_{i=1}^n \mathcal{F}_{it}$. The load-share model can be described by specifying the failure intensities as

$$\begin{aligned} \Pr\{dN_i(t) = 1 | \mathcal{F}_{it-}\} \\ = r(t) Y_i(t) \gamma[N_i(t-)] dt, \quad i = 1, \dots, n \end{aligned} \quad (9)$$

Note that

$$M_i(t) = N_i(t) - \int_0^t \gamma[N_i(u-)] r(u) Y_i(u) du \quad (10)$$

is a vector of orthogonal square-integrable zero-mean martingales. See, for example, Andersen *et al.* [14]. In terms of $\{(N_i(w), Y_i(w)), 0 \leq w \leq \tau\}$: $i = 1, 2, \dots, n$, the likelihood is

$$\begin{aligned} L(R(\cdot), \boldsymbol{\gamma}) \\ = \left\{ \prod_{i=1}^n \prod_{0 \leq w \leq \tau} \pi [Y_i(w) \gamma[N_i(w-)] dR(w)]^{dN_i(w)} \right\} \\ \times \exp \left\{ - \int_0^\tau Y_i(w) \gamma[N_i(w-)] dR(w) \right\} \end{aligned} \quad (11)$$

We can estimate $R(\cdot)$ from the equation (10) by fixing $\boldsymbol{\gamma}$, in $\hat{R}(\cdot; \boldsymbol{\gamma})$. By plugging $\hat{R}(\cdot; \boldsymbol{\gamma})$ into the equation (10), we have the profile likelihood $L_p(\boldsymbol{\gamma})$ for $\boldsymbol{\gamma}$, which is then maximized in $\boldsymbol{\gamma}$ to obtain the estimator $\hat{\boldsymbol{\gamma}}$. The semiparametric estimator of $R(\cdot)$ is $\hat{R}(\cdot) = \hat{R}(\cdot; \hat{\boldsymbol{\gamma}})$. To estimate R this way, we define $J(w) = I(\sum_{i=1}^n Y_i(w) > 0)$, where $J(w) = 0$ indicates all nk components have already failed at time w . If $\boldsymbol{\gamma}$ is known, by using the zero-mean property of the martingale $\sum_{i=1}^n M_i(\cdot)$, we have

$$\hat{R}(s; \boldsymbol{\gamma}) = \int_0^s \frac{J(w) dN(w)}{\sum_{i=1}^n Y_i(w) \gamma[N_i(w-)]} \quad (12)$$

This is analogous to the derivation of the Nelson-Aalen estimator in Aalen [15].

The estimator in the equation (12) is a generalized Nelson-Aalen estimator, and is similar in structure to the hazard function estimator for tensile strengths derived by Rydeń [10]. To obtain the estimator of $R(\cdot)$ for the more general case where γ is unknown, we first obtain the profile likelihood for γ by plugging in $\hat{R}(\cdot; \gamma)$ given in equation (12) into the likelihood function in equation (10). From equation (11) and equation (12) we obtain the *profile* likelihood to be

$$L_p(s; \gamma) = \prod_{i=1}^n \pi_{0 \leq w \leq s} \left[\frac{Y_i(w) \gamma [N_i(w-)]}{\sum_{l=1}^n Y_l(w) \gamma [N_l(w-)]} \right]^{dN_i(w)} \quad (13)$$

This profile likelihood is maximized with respect to γ to obtain $\hat{\gamma}$, which is then plugged in into $\hat{R}(\cdot; \gamma)$ to obtain the semiparametric estimator of R given by

$$\hat{R}(s) = \hat{R}(s; \hat{\gamma}) \quad (14)$$

By virtue of the product representation of $\bar{F} = 1 - F$ given by $\bar{F}(s) = \prod_{0 \leq w \leq s} [1 - R(dw)]$, we can estimate $\bar{F}$ with

$$\hat{\bar{F}}(s) = \prod_{0 \leq w \leq s} [1 - \hat{R}(dw)] \quad (15)$$

The solution to the nonparametric MLE is detailed in Kvam and Peña [11], and asymptotic properties for $\hat{R}$ and γ are discussed in the section titled “Time-to-Failure Models” of that paper.

Maintenance Optimization

Introduction

As the cost of maintenance is continuously increasing [1], a scientific approach to maintenance optimization is of considerable interest. Maintenance optimization is the problem of determining cost-optimal maintenance decisions for an object (system or structure or one of its components) to ensure a safe and economic operation. An important concept in maintenance optimization is that of life-cycle costing (*see Life Cycle Costs and Reliability Engineering*), where the total cost of design, building, maintenance, and demolition is considered over the entire life span of the object in question. In optimizing maintenance, the uncertainties in the time to failure and/or the deteriorating condition should be taken into account (*see Stochastic Deterioration*). Many maintenance models, under uncertain deterioration, have been developed in various fields of engineering and a large number of articles, mainly focusing on the mathematical aspects, have been published [1–12]. Herein, a number of probabilistic models for optimizing the life-cycle cost of deteriorating objects are reviewed.

Maintenance optimization techniques are applicable in the design phase and the application phase of the life span of an object. In the design phase, the initial cost of investment has to be balanced against the future cost of maintenance by optimizing the design: the larger the initial resistance, the higher the cost of investment, but the lower the cost of maintenance. In the application phase, the costs of inspection and preventive maintenance (PM) have to be balanced against the costs of corrective maintenance (CM) and failure, by optimizing intervals of inspection and PM: the more PM is carried out, the higher the costs of inspection and PM, but the smaller the costs of CM and failure.

Maintenance

Maintenance Strategies

Usually, maintenance is defined as a combination of actions carried out to restore a component to, or to “renew” it to, a specified condition in which

the component can perform its required functions. Inspections, replacements, perfect repairs, partial repairs (lifetime-extending maintenance), and minimal repairs (restoring the component to its prefailure state) are possible maintenance actions. Roughly, there are two types of maintenance: corrective maintenance (after failure) and preventive maintenance (mainly before failure). The decision diagram for the choice between CM and PM is given in Figure 1.

PM can be further subdivided into: time-based maintenance carried out at regular intervals of time, use-based maintenance carried out after a fixed cumulative use, operation or load, and condition-based maintenance (CBM) carried out at times determined by (non)periodic inspection or continuous monitoring of a component's condition. According to Moubray [13], industrial maintenance changed from corrective to preventive in 1950s; initially time-based maintenance in 1960s (such as equipment overhauls at fixed intervals) and from 1970s on more CBM (such as condition monitoring). The above maintenance strategies can be applied to a single component or groups of components.

To determine optimal maintenance decisions under stochastic deterioration (*see Stochastic Deterioration*), we distinguish two approaches [14, Chapter 1]: the actuarial approach based on the notion of lifetime (time to failure) and the physical approach based on the notion of failure due the stress exceeding the resistance (*see Stress–Strength Model*). The former is used to model time-based maintenance and the latter to model CBM.

Assumptions, Notations, and Abbreviations

In the material reviewed below, the following assumptions are made: inspection is perfect in the sense that deterioration will be observed with certainty; inspection, maintenance, and replacement take negligible time and do not degrade the component at hand.

In addition, the following notation will be used in the description of the models: c_P is the cost of preventive replacement or maintenance, c_F is the cost of corrective replacement or maintenance and failure, c_I is the cost of a single inspection, and c_U is the cost of unavailability per unit time in the event of an unrevealed failure.

Finally, the following standard abbreviations will be used for brevity of presentation: PM (preventive maintenance), CM (corrective maintenance), CBM

2 Maintenance Optimization

Figure 1 Decision diagram for corrective and preventive maintenance

(condition-based maintenance), and EEAC (expected equivalent average cost).

Renewal Reward Processes

Maintenance can often be modeled as a renewal process, whereby the renewals are the maintenance actions that bring a component back into its original condition or “good as new” state (*see Renewal Theory*). A renewal process $\{N(t), t \geq 0\}$ is a nonnegative integer-valued stochastic process that registers the successive renewals in the time interval $(0, t]$. Let $F(t)$ be the cumulative distribution function of the renewal time $T \geq 0$ and let $c(t)$ be the cost associated with a renewal at time t .

There are three cost-based criteria that can be used to compare maintenance decisions [15, Chapter 11]: (a) the expected average cost per unit time, (b) the expected discounted cost over an unbounded time horizon, and (c) the EEAC per unit time. Because the planned lifetime of most systems and structures is very long, maintenance decisions may be compared over an unbounded time horizon. For an overview on maintenance optimization over a bounded horizon, see [16].

Using renewal reward theory [17, Chapter 3], the expected average cost per unit time is

$$\lim_{t \rightarrow \infty} \frac{E(K(t))}{t} = \frac{\int_0^\infty c(t) dF(t)}{\int_0^\infty t dF(t)} = \frac{E(\text{cycle cost})}{E(\text{cycle length})} \quad (1)$$

where $E(K(t))$ represents the expected nondiscounted cost in the bounded time interval $(0, t]$. Let a renewal cycle be the time period between two

renewals, and recognize the numerator of equation (1) as the expected cycle cost and the denominator as the expected cycle length (mean lifetime).

To account for the time value of money, Samuelson [18] proposed to use the exponential discount function e^{-rt} with constant discount rate $r > 0$ for time $t \geq 0$. Using renewal reward theory with discounting [19, 20], the expected discounted cost over an unbounded horizon can be written as

$$c_0 + \lim_{t \rightarrow \infty} E(K(t, r)) = c_0 + \frac{\int_0^\infty e^{-rt} c(t) dF(t)}{1 - \int_0^\infty e^{-rt} dF(t)} = L(r) \quad (2)$$

where c_0 is the investment cost and $E(K(t, r))$ is the expected discounted cost in the bounded time interval $(0, t]$, $t > 0$. Similar results can be obtained for discrete-time **renewal processes** [21]. For renewal theory with other types of discounting (such as generalized hyperbolic or gamma discounting), see van der Weide *et al.* [20].

For the purpose of reserving budget for performing future maintenance actions, it is important to determine the amount of money these actions cost per unit time while taking the discounting into account. This cost is known as the *equivalent average cost per unit time* [15, Chapter 11]. The EEAC per unit time computed over an unbounded time horizon is defined as

$$EEAC = \lim_{t \rightarrow \infty} \frac{c_0 + E(K(t, r))}{\int_0^t e^{-rx} dx} = rL(r) \quad (3)$$

The EEAC per unit time can also be interpreted as a stream of fixed identical cost per unit time sufficient

to recover all the necessary discounted cost. As r tends to zero from above, the EEAC approaches the expected average cost per unit time [21]; that is,

$$\lim_{r \downarrow 0} \frac{E(K(t, r))}{\int_0^t e^{-rx} dx} = \frac{E(K(t, 0))}{t} \quad (4)$$

The cost-based criteria of discounted cost and EEAC are most suitable for balancing the initial building cost optimally against the future maintenance cost, because the contribution of the initial investment cost is not ignored (as opposed to the expected average cost per unit time). The criterion of the expected average cost per unit time can be used in situations in which no large investments are made (like inspections) and in which the time value of money is of no consequence. Often, it is preferable to spread the cost of maintenance over time and to use discounting. The area of optimizing maintenance through mathematical models based on lifetime distributions was founded in the early 1960s [2, 3]. Well-known decision models of this period are the age-replacement model and the block-replacement model.

Age Replacement

Under an age-replacement policy [2, Chapters 3–4], a replacement is carried out at age $k > 0$ (preventive replacement) *or* at failure (corrective replacement), whichever occurs first. Let the time to failure T have a cumulative distribution function $F(t)$. According to equation (1), the expected average cost of age replacement per unit time is

$$\lim_{t \rightarrow \infty} \frac{E(K(t))}{t} = \frac{c_F F(k) + c_P \bar{F}(k)}{\int_0^k t dF(t) + k \bar{F}(k)} \quad (5)$$

where k is the age-replacement interval and $0 < c_P \leq c_F$. The optimal age-replacement interval k^* is an interval for which the expected average cost per unit time is minimal. Note that PM only makes sense for deteriorating components (i.e., having increasing failure rates). According to equation (2) and Fox [22], the expected discounted cost of age replacement over

an unbounded horizon is

$$\begin{aligned} \lim_{t \rightarrow \infty} E(K(t, r)) &= \frac{c_F \int_0^k e^{-rt} dF(t) + c_P e^{-rk} \bar{F}(k)}{1 - \left[\int_0^k e^{-rt} dF(t) + e^{-rk} \bar{F}(k) \right]} \\ &= L(r) \end{aligned} \quad (6)$$

Note that the replacement model can also be applied for determining an optimal component in the design phase, which balances the initial cost of investment c_P optimally against the future cost of maintenance, by adding c_P to equation (6). The age-replacement model is one of the maintenance optimization models that has been applied most [1, 9]. For example, it has been extended with the possibility of lifetime-extending maintenance in [23].

Block Replacement

Under a block-replacement policy (*see Block Replacement*), a replacement is carried out at failure (corrective replacement) *and* periodically at the times $k, 2k, 3k, \dots$ (preventive replacement). Let the failure times $T_1, T_2, T_3, \dots$ be nonnegative, independent, identically distributed, random quantities having the cumulative distribution function $F(t)$. The expected average cost of block replacement per unit time when the decision maker chooses block-replacement interval k is

$$\lim_{t \rightarrow \infty} \frac{E(K(t))}{t} = \frac{c_F E(N(k)) + c_P}{k} \quad (7)$$

where $E(N(t))$ is the expected number of failures in $(0, t]$:

$$N(t) = \max\{j \mid S_j \leq t\} = \sum_{i=1}^{\infty} 1_{\{S_i \leq t\}}, \quad t \geq 0 \quad (8)$$

where $S_j = T_1 + \dots + T_j$, $j = 1, 2, \dots$, and 1_A denotes the indicator function of the set A . The expected discounted cost of block replacement over an unbounded horizon when the decision maker chooses block-replacement interval k is

$$\lim_{t \rightarrow \infty} E(K(t, r)) = \frac{c_F E(N(k, r)) + c_P e^{-rk}}{1 - e^{-rk}} \quad (9)$$

4 Maintenance Optimization

where $E(N(t, r))$ is the expected number of “discounted failures” in $(0, t]$; that is,

$$E(N(t, r)) = E\left(\sum_{i=1}^{\infty} e^{-rS_i} 1_{\{S_i \leq t\}}\right), \quad t \geq 0 \quad (10)$$

The block-replacement policy may be modified by performing a **minimal repair** when a component fails in the block interval [24]. Assuming the failure rate h before and after the minimal repair to be identical, then $E(N(k)) = \int_0^k h(t) dt$ and $E(N(k, r)) = \int_0^k e^{-rt} h(t) dt$.

Inspection to Detect Failures

The age- and block-replacement models assume failures to be detected immediately (revealed failures). When failures are detected only by inspection (unrevealed failures), then a different maintenance model should be used. For this purpose, we assume that the inspection times are $0 = t_0 < t_1 < t_2 < \dots$. A renewal is assumed when inspection reveals failure. According to Barlow and Proschan [2, Chapter 4], the expected costs of inspection and unavailability can be written as

$$E(\text{cycle cost}) = \sum_{j=1}^{\infty} \int_{t_{j-1}}^{t_j} [c_I j + c_U(t_j - t)] dF(t) + c_F \quad (11)$$

and the expected renewal time as

$$E(\text{cycle length}) = \sum_{j=1}^{\infty} \int_{t_{j-1}}^{t_j} t_j dF(t) \quad (12)$$

Another inspection model is the delay-time model [25, 26], which assumes the failure process to have two stages: the first stage at which the component is functioning well and the second stage at which the component is still functioning but defective, in the sense that failure can be expected soon. Periodic inspection is performed to reveal whether a component is defective or not with inspection interval τ . The time interval between the first moment at which a defect can be noticed until the time of failure is called the *delay time* and is assumed to have cumulative distribution function G . The occurrence process of defects is assumed to be a Poisson with a

rate λ . Using equation (1), the expected average cost per unit time can be written as

$$\frac{E(\text{cycle cost})}{E(\text{cycle length})} = \frac{c_I + c_F \int_0^{\tau} \lambda G(\tau - x) dx}{\tau} \quad (13)$$

Multicomponent Maintenance

When production downtime occurs or when other system component failures occur requiring downtime, maintenance opportunities may be presented for all components. When such is the case, opportunity-based maintenance models are used. These approaches use either age [27–31] or block [32, 33] **replacement strategies** with opportunity times described by a renewal, Markov or **Poisson process**.

Dependence among components can arise due to economies of scale for maintenance cost, structural relationships, or stochastic dependence of failure times [34]. Accounting for these types of dependencies has also been an important research area in maintenance optimization. Reviews of models for multicomponent maintenance can be found in [8, 35] (see **Multicomponent Maintenance**).

Condition-based Maintenance

Due to the usual lack of failure data, a reliability approach solely based on lifetime distributions is unsatisfactory. If possible, it is recommended to model deterioration in terms of a time-dependent stochastic process $\{X(t), t \geq 0\}$ where $X(t)$ is a random quantity for all $t \geq 0$. The deterioration as a function of time t , $X(t)$, is usually assumed to be a Markov process [2, Chapter 5] (see **Markov Processes**). Classes of Markov processes which are useful for modeling stochastic deterioration are discrete-time Markov processes having a finite or countable state space called *Markov chains* and continuous-time nondecreasing Markov processes with independent increments such as the compound Poisson process and the gamma process. Compound Poisson processes (gamma processes) are jump processes with a finite (infinite) number of jumps in a bounded time interval (for a sample path of the gamma process, see Figure 2 taken from [36]). Compound Poisson processes are suitable for modeling

Figure 2 Condition-based maintenance model under gamma process deterioration

damage due to sporadic shocks and gamma processes for describing gradual damage by continuous use [36].

Monotone Jump Process. Modeling the deterioration as a monotone stochastic jump process is especially suited when inspections are involved [36]. In optimizing periodic inspection, the two decision variables are the inspection interval τ and the PM level ρ (Figure 2). Such a policy is called a *control-limit policy* with the PM level called the *control limit* [11]. The deterioration is inspected periodically (i.e., $t_j = j\tau$, $j = 1, 2, \dots$) and is regarded as a gamma process. At an inspection, the object can be in a functional (good), marginal, or failed state. If the object is found to be in a functional state, no maintenance is required and only the cost of the inspection is incurred. If it is found to be in a marginal state, the cost of PM is added to the cost of the inspection. For an object in failed state, there are two scenarios: either the failure is immediately noticed at the time of occurrence [37–41], without the necessity of an inspection, or failure is only detected at the next planned inspection [42–44]. In the first case, only the cost of CM is incurred and in the second case, the cost of the inspection and unavailability has to be included as well. A renewal can be PM or CM and it brings the object back to its “good as new” condition. The optimal maintenance decision is determined by minimizing the long-term expected average cost per unit time in equation (1).

When a failure is detected immediately, the expected renewal-cycle cost is the sum of the costs of all inspections during the cycle and either PM or CM:

$$E(\text{cycle cost}) = \sum_{j=1}^{\infty} [(jc_I + c_P) \Pr \{\text{PM in } (t_{j-1}, t_j]\} + ((j-1)c_I + c_F) \times \Pr \{\text{CM in } (t_{j-1}, t_j]\}] \quad (14)$$

In terms of the deterioration process $X(t)$, the event $\{\text{PM in } (t_{j-1}, t_j]\}$ means PM at the j th inspection and is equivalent to $\{r_0 - X(t_{j-1}) \geq \rho, s \leq r_0 - X(t_j) < \rho\}$. The event $\{\text{CM in } (t_{j-1}, t_j]\}$ means CM during the j th inspection interval, which is equivalent to $\{r_0 - X(t_{j-1}) \geq \rho, r_0 - X(t_j) < s\}$. In a similar way, the expected renewal-cycle length is

$$E(\text{cycle length}) = \sum_{j=1}^{\infty} [t_j \Pr \{\text{PM in } (t_{j-1}, t_j]\} + E(T_F; \text{CM in } (t_{j-1}, t_j])] \quad (15)$$

where T_F is the time to failure. Extensions and variations of the CBM model with failures detected immediately include discounting [39, 40], non-periodic inspection [40, 45], and partial or **imperfect repair** [46].

When a failure is detected only by inspection, the object is renewed when an inspection reveals either that the PM level ρ is crossed while no failure has occurred (PM) or that the failure level s is crossed (CM). The expected cycle cost in equation (14) should now be extended with the cost of the inspection at which failure is detected and a penalization for the unavailability of the object due to the unrevealed failure being

$$\sum_{j=1}^{\infty} [c_I \Pr \{\text{CM in } (t_{j-1}, t_j]\} + c_U E(t_j - T_F; \text{CM in } (t_{j-1}, t_j])] \quad (16)$$

where c_U is the cost of unavailability per unit time. The expected cycle length is

$$E(\text{cycle length}) = \sum_{j=1}^{\infty} t_j \Pr \{\text{PM or CM in } (t_{j-1}, t_j]\} \quad (17)$$

Extensions and variations of the CBM model with failures detected only by inspection include nonperiodic inspection [47, 48], **optimal design** [49], and damage initiation [50]. A CBM model with deterioration described as a compound Poisson process can be found in Zuckerman [44].

Markov Decision Process. When a finite or countable state space is assumed, implying that the condition of a component can be in any one of $n \geq 0$ discrete states, a Markov-chain model can be used (see **Maintenance and Markov Decision Models**). The condition-based inspection model described in the previous section can also be applied when deterioration is modeled by a finite-state Markov process. See [51] for an application to bridge inspections. However, a more common optimization framework for these processes are the so-called Markov decision processes.

Decisions about an optimal policy for maintenance actions are made on a finite set of actions A and costs $C(i, a)$, which are incurred when the process is in state i and action $a \in A$ is taken. The costs are assumed to be bounded and a policy is defined to be any rule for choosing actions. When the process is in state i at time $t = 0, 1, 2, \dots$ and an action a is taken, the process moves into state j after one unit of time with probability

$$P_{ij}(a) = \Pr\{X_{t+1} = j | X_t = i, a_t = a\} \quad (18)$$

Like for regular Markov chains, this transition probability does not depend on the state history. If a stationary policy is selected, then this process is a Markov decision process. A stationary policy arises when the decision for an action only depends on the current state of the process and not on the time at which the action is performed.

Given that the state of the process at times $0, 1, \dots$ is modeled by a Markov decision process $X_0, X_1, \dots$ governed by the transition probabilities $P_{ij}(a)$, the optimization of inspection and/or maintenance policies using this process can be performed. For example, when the object is in state i the expected discounted costs over an unbounded horizon are given by the recurrent relation

$$V_\alpha(i) = C(i, a) + \alpha \sum_{j=1}^n P_{ij}(a) V_\alpha(j) \quad (19)$$

where $\alpha = 1/(1+r)$ is the discount factor for one unit of time, r the discount rate, and V_α the value function using α . Starting from state i , $V_\alpha(i)$ gives us the cost of performing an action a given by $C(i, a)$ and adds the expected discounted costs of moving into another state one unit of time later with probability $P_{ij}(a)$. The discounted costs over an unbounded horizon associated with a start in state j are given by $V_\alpha(j)$, therefore, equation (19) is a recursive equation. The choice for the action a is determined by the maintenance policy and also includes no repair.

A cost-optimal decision can now be found by minimizing equation (19) with respect to the action a . There are a number of ways to find this optimal solution. One of these is the so-called policy improvement algorithm, where equation (19) is calculated for increasingly better policies until no more improvement can be made. Also, it is possible to formulate the minimization problem as a linear programming problem. This is used in the Arizona pavement management system [52] and the PONTIS bridge management system [53]. As Golabi [54] illustrates, we can choose to maximize the condition of the road system under a budget constraint or we can minimize the maintenance cost under a minimum safety constraint. This can be achieved by using the original linear programming formulation or with its dual formulation.

The difference between the use of the condition-based inspection model from the previous section and Markov decision processes lies primarily in the fact that the latter approach is used to make a decision about what to do at fixed times $t = 0, 1, 2, \dots$. The condition-based inspection model has a fixed policy, namely, do nothing if the condition is functional, do a preventative repair if the condition is marginal, and do a corrective repair if the object is in a failed condition. Given this policy, the inspection interval and the thresholds for marginal and failed conditions may be optimized. The decision is therefore not what to do, but when to do it.

Adaptive Maintenance Policies

In most cases, the maintenance optimization approaches are developed under the assumption that the parameters of the process are known (or estimated) within a degree of certainty. Adaptive methods for

maintenance optimization using a Bayes approach where **prior distributions** are formulated for distribution parameters and updated as data becomes available have been proposed for only a few basic models. Wilson and Benmerzouga [55] have used this approach for analysis of group replacement strategies for parallel components with exponential failure times. Mazzuchi and Soyer [56] propose a Bayes approach for the standard age- and block-replacement model where the underlying failure time distribution is Weibull. There are several extensions in the literature. In Markov decision processes, Bayes theorem can be applied to update prior distributions on transition probabilities elicited from engineers with inspections [57]. Finally, Kallen and van Noortwijk [41] provide a Bayes analysis for a periodic (imperfect) inspection and maintenance plan where the deterioration process is modeled by a gamma process.

Expert Opinion in Reliability

Introduction

Expert opinion can be a useful source of information for assessing reliability, provided it is obtained in a manner that minimizes common sources of **bias** and ambiguity. The term for obtaining expert opinion in this manner is *elicitation*. In reliability assessment, elicitation is most often directed at two distinct elements of expert opinion: expert *judgment* about the value of a specific quantity or probability of interest, or expert *knowledge* about the dependency structure of a system.

Expert opinion elicitation is typically used in one of two ways. First, it is used in situations where data are scarce, but a relevant body of expertise exists. This might be the case, for example, when assessing the reliability of a new type of system where test data are not yet available, but there is experience with similar systems, and the relevant physical mechanisms and design principles are known. Second, expert opinion can be a source of additional information even where a body of data already exists. For example, elicitation of expert knowledge about system dependencies can reveal interactions between parts that have not yet been quantified or formally documented, but are relevant to reliability. Similarly, experts may condition their judgment about part reliability on a wider range of contextual information than can be captured in a particular test. As a result, statistically combining expert judgment with test data may provide more information about reliability than test data alone. In Bayesian statistical analyses, expert judgment elicitation is often used to obtain **prior distributions** which are then combined with other data to generate posterior distributions for use in assessing system reliability [1].

The first step in successful elicitation of expert opinion is the identification of relevant experts. The term *expert* may be applied to a wide range of individuals, not all of whom are appropriate elicitation subjects. In general, for the purposes of expert opinion elicitation, the relevant experts are those with *contributory expertise* in the problem area [2]. These are individuals who have experience either with the specific system in question, or with similar

systems; who have experience directly related to the problem at hand; and who are (or were recently) active participants in technical work. Expertise in this sense may or may not be related to formal technical qualifications (such as an academic degree), although it is usually related to experience over some period of time in the relevant technical area. Experts are also usually chosen based on recognition of their expertise within the relevant technical community, as this can be crucial to the credibility of the elicitation results.

When quantitative results are desired, elicitation of expert opinion is usually carried out according to a formalized list of questions, which the experts may be asked to answer verbally or in writing. Formulating a useful set of questions is an important aspect of elicitation methodology. Overly complex or ambiguous questions, or questions that require the expert to make multiple assumptions, have been shown to yield less accurate responses. For this reason, general questions are often decomposed into a series of simpler questions that depend on only a few specified assumptions. To develop such a list of questions, the persons conducting the elicitation often work in collaboration with one or more *advisory experts*. These experts assist in defining the problem space and refining the elicitation questionnaire, providing a check on the quality of the questions before they are administered to a larger set of experts. Because many technical experts do not have expertise in statistics or reliability, one role of the advisory expert is to translate reliability terms into technical terms familiar to the expert community. The quality of the questions can also be assessed during the elicitation process by monitoring the experts' problem-solving processes, for example by asking them to explicitly report on the reasoning and assumptions behind their responses [3].

Expert opinion can be aggregated in a variety of ways. Elicitation can be conducted with each expert individually, and their responses aggregated mathematically [3, 4]. Expert opinions can also be aggregated behaviorally by conducting group elicitations or through the use of other methods in which experts try to reach consensus, such as the Delphi method [3, 5].

Expert Judgment Elicitation

Expert judgment elicitation is typically focused on obtaining the best judgment of an expert about the

2 Expert Opinion in Reliability

value of a quantity or probability of interest [6]. For example, an expert might be asked to estimate the likely failure temperature of a part, or could be asked to estimate the probability that a part will fail at a given temperature. The expert is most often asked to provide a point estimate, but may also be asked to estimate uncertainty bounds or provide a complete probability distribution.

The main driver for elicitation methodology is the need to identify and mitigate bias in experts' responses. While some biases are problem specific, research in the social and behavioral sciences has documented a number of common biases in the way both experts and laypeople answer elicitation questions. It is useful to distinguish three forms of bias in elicitation. *Cognitive bias* occurs when expert reasoning fails to adhere to some objective standard, such as the laws of probability, due to inherent limitations on the brain's ability to process information. *Motivational bias* occurs when experts alter their responses (often unconsciously) in response to the elicitation setting, so that their responses do not reflect their true subjective beliefs. For example, experts may downplay uncertainties in order to provide more authoritative answers if they believe that is what the interviewer is looking for. *Interviewer bias* may also be introduced into the elicitation process if the person conducting the elicitation or analyzing the results misinterprets expert responses or steers them toward a preferred answer [3].

Because motivational bias and interviewer bias can only be measured in relation to subjective standards, methods for mitigating these forms of bias are not highly formalized; a general principle is to ask nondirective questions that carefully avoid leading the expert toward a particular answer. Cognitive bias, however, has been the subject of extensive behavioral research, and a number of specific techniques have been developed to minimize it.

Some of the most significant types of cognitive bias are availability, anchoring, and inconsistency [4, 7–9]. *Availability bias* refers to experts focusing on what they have seen prior to the exclusion of the full range of what is possible. So an expert may report an inappropriately high probability of a part failing in a way previously observed, especially if it was a dramatic failure, while discounting the probability of more likely, more mundane failures. Group elicitation methods can help counter this bias by allowing experts to share information. Free

association methods, in which experts are asked to quickly generate a list of factors bearing on a question, are also used [3].

Anchoring bias is the tendency, when faced with new information, to update quantities conservatively from an initial estimated value, rather than comprehensively reassessing the problem. This can occur when experts are asked to estimate the probability of an event based on various preconditions; their answer to the first question is likely to influence their answers to subsequent questions. Similarly, if an expert is asked to estimate probabilities for a string of highly unlikely events, they may then have difficulty giving a good estimate of a more likely event. Providing feedback from other experts, such as through group elicitation methods or the Delphi method, can inhibit anchoring. Elicitation questions can also explicitly request that experts not base their answers on previous responses [3].

The inconsistency bias appears in complex elicitations where experts may not be able to keep track of all previous answers, assumed rules, and hypothetical frameworks in a way that allows them to provide consistent estimates. This bias is related to memory, so one way it can be addressed is by frequently reminding elicitation subjects of key definitions and assumptions during the elicitation process. Experts may also be provided with documentation of previous responses so they can monitor their own consistency [3]. Pairwise comparison methods such as the Saaty Analytical Hierarchy Process, can also be used to monitor consistency [10].

Elicitation Methods

Elicitation methods can be categorized by what part of the probability distribution they are designed to capture: center value, interval, or functional form. Examples of eliciting a center value include asking an expert for a single-value estimate of a physical quantity or probability of an event occurring. This can be done on a continuous or discrete scale. Asking the expert to give a probability between 0 and 1 or a temperature in degrees Celsius are examples of using a continuous scale. A discrete scale is one that breaks the range of possible values into a series of intervals. For example, the Sherman Kent scale breaks probabilities into five categories: nearly impossible, improbable, even chance, probable, and nearly certain, which are specified to correspond

to percent chances of approximately 10, 30, 50, 70, and 90%. Experts may be more comfortable providing probability estimates as percent chances or, particularly for small probabilities, as odds ratios (e.g., 1/100) [3]. An indirect method for eliciting center values, known as the *interval technique*, is to specify the range of possible values of a variable, and then ask experts to adjust a dividing point until the chances of the value being above or below that point are approximately equal, which will be the likely median value [7, 11]. Availability and anchoring are potential biases in eliciting center values.

Interval elicitation is generally used to elicit uncertainty in experts' estimates. This can be done in two ways. First, a probability interval can be specified and the expert can be asked which values fall within the interval. For example, in addition to the most likely temperature at which a part might fail, the interviewer might ask for upper and lower bounds on failure temperature. The interval may be specified in terms of absolute maximum and minimum values, or in terms of **confidence intervals** (e.g., specifying a 90% chance of failure within the interval). A second approach is to specify a range of values and ask the expert what the chances of failure are within that range [7, 11]. For example, if a part specification provides a nominal range of temperature tolerance, this could be verified by asking the expert what he or she thinks the odds are of the part failing if its temperature stays within that range [12]. Experts frequently underestimate uncertainty, a form of anchoring bias [3, 13]. Elicitation methods designed to counter availability and anchoring may be used to counteract this tendency.

Elicitation methods have also been developed to capture the overall shape of a probability distribution. Statistically, sophisticated experts can be asked to draw the **probability density function** or cumulative distribution function directly. Distributions can be approximated by aggregating point estimates – for example, the probability distribution on failure temperature for a part can be assembled by asking for the odds of failure at various points in the temperature range. Similarly, fractile methods ask the expert to estimate the value of a parameter that has a certain probability of occurring (e.g., 0.25) at several points between 0 and 1, and then aggregate these to approximate a probability distribution. The interval technique, mentioned above, may be extended to estimate **quartiles** or even smaller intervals. Methods

for eliciting the shape of probability functions are attractive from a statistical point of view because they provide the most information possible for further analysis. However, they are complex and time consuming, which may lead to problems with inconsistency, and ask for a level of discrimination about probabilities that many experts may not possess.

Elicitation of System Dependencies

Often what an expert knows in the context of reliability goes beyond what they can estimate about a single probability or range of values. Elicitation of expert knowledge about system dependencies focuses on determining the structure of variables that make up a reliability model, and the degree to which system outcomes can be explained in terms of combinations of component measurements.

Eliciting system knowledge is a challenge for a variety of reasons. Systems are often complex: frequently no single person truly understands how the entire system works and what all measures gathered about the system mean. In addition, for all but the most trivial systems, experts typically have incomplete or conflicting knowledge about these factors. Generally, system reliability depends on part characteristics and interactions that may not be documented in formal system representations.

If a system is made up of several components, it is generally necessary to elicit what experts know about dependencies within the system (i.e., model structure) in order to accurately assess reliability. Take the trivial case of a two-component system with the probability of each component functioning properly as $P1$ and $P2$. Unless it is known whether or not these components are in a serial relationship, the system reliability cannot be estimated as $P1 \times P2$ – under different system logical structures, with different assumptions about system control logic, the overall system reliability could alternatively be maximum ($P1, P2$), or $P1 + (1 - P1) \times P2$, etc.

In addition, once the assumption that the reliability of $P1$ and $P2$ are independent is violated, a host of additional unavoidable elicitation complications are introduced. For example, $P1$ and $P2$ may have more than one failure mode, or system components may have more than two states. In such a case, it may be necessary to model not only whether a component fails, but how the failure may cascade

along different pathways and with different overall system level effects through to other components. *P1* may fail gracefully, allowing *P2* to pick up the slack, or *P1* may explode, greatly increasing the odds that *P2* will also fail.

Accordingly, unless a set of fairly stringent assumptions about a system's internal logic can be sustained (i.e., serial relationships, binary states, stable and fixed relationships, and no changes with age), eliciting expert knowledge of dependencies is not a trivial task [14]. In the case of some systems, these assumptions are not impossibly stringent. Electrical circuits and some types of electronics, for example, lend themselves to models that incorporate these assumptions. Modeling a great many other types of systems, especially those involving human interactions or extended life cycles, greatly stresses all of these assumptions. Military systems and electrical power facilities are examples of systems that face varying conditions over their lifetimes.

These challenges divide the elicitation of expert knowledge about system dependencies into two discernable tasks: eliciting knowledge about system structure directly from experts, and harvesting information that experts and their communities have encoded in representations of the system (e.g., engineering block diagrams, event timelines, flowcharts, etc.).

Eliciting system structure depends on choosing a system representation method that will support a successful description of the system by (a) successfully capturing the complexities of component relationships, while (b) presenting information that is meaningful both to system operators (generally engineers) and reliability modelers (generally statisticians). If the system is fairly simple, it may be possible to sketch and annotate a representation of important components and relationships on a piece of paper in a single conversation. If the system is more complicated, elicitation may involve multiple experts with focused knowledge of different parts of the system. In such cases, a more formalized approach is helpful. For example, software has been developed that enables representation of the parts of a system and their interactions as a collection of boxes and connecting lines, and also keeps track of those parts and interactions in a database. A more complicated system may also require more time iterating representations with the experts over several conversations

as they think through and come to consensus on the functional dependencies [15].

There are a number of possible approaches to developing representations of system dependencies. A typical elicitation process might run as follows:

First, elicit a list (or ontology) of possible objects that will appear in the system representations. This ontology dictates what relationships are permissible and how objects are named. Among other things, this serves to prevent confusion about similar parts – for example, whether “Battery A” on diagram 4 is the same as “battery-a” on diagram 64. Next, create a high-level diagram that only shows the main components, and indicates how these components interact. Then “drill down” into each of those high-level boxes and create a diagram of the parts that comprise that component, also noting interactions. Parts may appear on more than one diagram (e.g., a battery may provide electricity to more than one component).

Next, refine the representation by revisiting the interactions between the components/parts and formalizing what one box provides to the next. Additionally, note failure modes for each component/part and how they affect the interactions. Iterating through this process, experts may change their minds about whether a particular concept is a part or a relationship, and they may remember new parts as they try to explain the functionality of the system.

An alternate approach is to first diagram the timeline of the key events in a system's operation (e.g., fill with water, add detergent, agitate, drain, rinse, drain, spin), then diagram system functions that must occur to make these events happen, and then finally identify components/parts that have to work in order for the functions to transpire [16].

Either of these approaches generates a model structure to work from: a **fault tree** structure if component/part logic is binary or a Bayes network structure if the logic is multistate. Having such a diagrammatic representation of system components/parts and relationships can be a valuable starting point for eliciting point values and distributions.

Seldom do systems engineers have a functional representation of a system in hand and ready for the reliability modeler to use. However, they often have similar representations: process representations like block flow diagrams, IDEF0, or flowcharts; outcome system behavior summaries like event or fault trees; or time logic summaries like timelines or GANT and PERT charts. All of these contain valuable knowledge

about system structure and dependencies that has already been encoded by the expert community. A study of these documents before an elicitation, or a discussion of these documents during an elicitation, can accelerate the process of building an ontology, functionally grouping parts, and understanding relationships and failure modes.

The purpose of eliciting expert judgment and expert knowledge of system dependencies is to provide information about likely system performance and to translate system dependencies into some kind of probabilistic fault structure. As part of any reliability modeling effort, many types of data may need to be stitched together to produce a reliability estimate (e.g., full-system or component test data, computer models, surrogate data, expert opinion, etc.) [17]. Expert opinion is most useful and defensible when it is collected according to scrupulous and documented methods that take into account potential biases and how the experts understand the problem.

Multivariate Age and Multivariate Renewal Replacement

Introduction

For the past four decades, many researchers have shown interest in the study of **maintenance policies** for systems with stochastic failure. One major reason for this is that these policies can be applied to many areas such as the military, industry, health, and environment.

Generally speaking, in a repairable system, components are repaired or replaced upon failure. There will be cases where the interruption caused in service failure of the system is more costly than the replacement of the components which are in service. Thus, in order to avoid the high cost associated with a failure of the system, an alternative approach is not to wait for components to fail, but to replace or repair them in accordance with a predetermined maintenance schedule. Such preventive maintenance policies reduce unexpected incidents of component or system failure. A large part of reliability theory deals with replacement of single-component systems. Two of the popular **replacement policies** are (a) age- and (b) **block-replacement** policies. Under age replacement a system is replaced only if it has either failed or attained an age, say T . When systems can be replaced in blocks, an example being the replacement of street lamps, a block-replacement policy is used. Here the system is replaced only if either it has failed or the current time is an integer multiple of the block-replacement interval, say T . Many papers have dealt with a stochastic comparison of the number of failures and replacements under these policies. Several authors have also studied different optimal policies under age and block replacement policies. We refer you to Barlow and Proschan [1], Lam [2], Valdez-Flores and Feldman [3] and Shaked and Zhu [4].

As systems become more complicated and require new technologies and methodologies, more sophisticated maintenance policies are needed to solve the maintenance problems. More specifically, it is quite common to find systems consisting of k components which are related. In such cases a legitimate question is: when to replace the components? Obviously,

the classical age-and block-replacement policies are unsuitable for such situations, since they only deal with a single component or system. Here, our focus is strictly on the age replacement policy. Also, our survey is confined to multivariate versions of age replacement policies as well as optimal age replacement policies.

Throughout this article “increasing” means “non-decreasing” and “decreasing” means “nonincreasing”.

Multivariate Age and Multivariate Renewal Replacements

Consider a system consisting of k components that are related. It is assumed that there are many identical components in stock to every component of this system. Below we describe the following two replacement policies, which are extensions of age replacement and ordinary renewal policies to the multivariate case. For more details see Ebrahimi [5].

Definition 1

1. Under a multivariate age replacement (MAR) policy, the component $i, i = 1, \dots, k$, of a system is replaced either at age T_i , or upon its failure. We refer to this as the MAR at $(T_1, \dots, T_k)$;
2. Under a multivariate renewal replacement (MRR), the component $i, i = 1, 2, \dots, k$, is replaced upon its failure.

To avoid complexity, we confine our attention to the case where $k = 2$. We define the following counting processes:

$N_i(t)$ = the number of component i failures in $(0, t]$ under MRR, $i = 1, 2$; $N_A(t; i, T) =$ the number of component i failures in $(0, t]$ under a MAR $(T, T), i = 1, 2$.

We let X_1 and X_2 be two non-negative continuous random variables representing the times to failure of new components 1 and 2, respectively. We also let $\bar{F}(x_1, x_2) = P(X_1 > x_1, X_2 > x_2)$ be the joint survival function of X_1 and X_2 and $\bar{F}_{X_i}(x_i) = P(X_i > x_i)$ be the marginal survival function of $X_i, i = 1, 2$. Here, $\bar{F}(0, 0) = \bar{F}_{X_1}(0) = \bar{F}_{X_2}(0) = 1$ and $\bar{F}(\infty, \infty) = \bar{F}_{X_1}(\infty) = \bar{F}_{X_2}(\infty) = 0$. It is assumed that as soon as a component of the system fails or it reaches the age T it will be replaced by a new and identical component whose lifetime is independent of the replaced component but is

2 Multivariate Age and Multivariate Renewal Replacement

dependent on the lifetimes of the components that are currently in service. It is also assumed that the replacement time (the time it takes to replace either component) is negligible. We denote the conditional survival function of X_1 given $X_2 > y$ and the conditional survival function of X_2 given $X_1 > y$ by

$$\bar{H}_y^{(1)}(x) = P(X_1 > x | X_2 > y) \quad (1)$$

and

$$\bar{H}_y^{(2)}(x) = P(X_2 > x | X_1 > y) \quad (2)$$

respectively.

We let $W_i(j)$ and $Y_i(j)$ be the intervals between the $(j-1)$ th and j th arrivals of the processes $N_i(t)$ and $N_A(t; i, T)$, $i = 1, 2$ respectively. Now, one can show that under MRR

$$\begin{aligned} P(W_i(j) \geq w_i, i = 1, 2 | W_i(\ell) \\ = a_{i\ell}, \ell = 1, \dots, j-1, \\ i = 1, 2) = \bar{F}(w_1, w_2) \end{aligned} \quad (3)$$

and under MAR(T, T) for $\ell_i T \leq y_i < (\ell_i + 1)T$, $i = 1, 2$

$$\begin{aligned} P(Y_i(j) \geq y_i, i = 1, 2 | Y_i(\ell) = a_{i\ell}, \\ \ell = 1, \dots, j-1, i = 1, 2) \\ = (\bar{F}(T, T))^{\ell_1} (\bar{H}_{y_1 - \ell_1 T}^{(2)}(T))^{\ell_2 - \ell_1} \\ \times \bar{F}(y_1 - \ell_1 T, y_2 - \ell_2 T) \\ \text{if } \ell_1 \leq \ell_2 \text{ and} \\ = (\bar{F}(T, T))^{\ell_2} (\bar{H}_{y_2 - \ell_2 T}^{(1)}(T))^{\ell_1 - \ell_2} \\ \times \bar{F}(y_1 - \ell_1 T, y_2 - \ell_2 T) \end{aligned} \quad (4)$$

if $\ell_1 \geq \ell_2$, see Ebrahimi [5] for more details. It should be noted that the equation (4) can be generalized to the case $k > 2$ by defining conditional survival functions similar to equations (2) and (3) for all permutations of $X_1, X_2, \dots, X_k$.

Contrast between MAR and MRR

It is clear that the multivariate age planned replacements take into account the ages of the components. It is therefore of interest to compare it with MRR with respect to the number of failures.

The following result provides a stochastic comparison of failures experienced under MAR(T, T) and MRR.

Theorem 1 *If (a) $\bar{F}(x + t_1, x + t_2) \leq (\geq) \bar{F}(x, x)$ $\bar{F}(t_1, t_2)$ for all $x, t_1, t_2 \geq 0$, and $\bar{H}_y^{(i)}(t_1 + t_2) \leq (\geq) \bar{H}_y^{(i)}(t_1) \bar{H}_y^{(i)}(t_2)$, $i = 1, 2$, for all $y, t_1, t_2 \geq 0$, then $P(N_i(t_i) \leq n_i, i = 1, 2) \leq (\geq) P(N_A(t_i; 1, T) \leq n_i, i = 1, 2)$ for all $n_1, n_2, t_1, t_2 \geq 0$.*

Theorem 1 states that under the conditions (a($\leq$)) and (b($\leq$)) imposed on the joint survival function of X_1 and X_2 the number of failures under MAR is stochastically less than the number of failures under MRR. Next result studies the effect of varying the replacement interval under MAR.

Theorem 2 *If (a) $\bar{F}(x_1 + t_1, x_2 + t_2) \leq \bar{F}(x_1, x_2)$ $\bar{F}(t_1, t_2)$ for all $x_1, x_2, t_1, t_2 \geq 0$ and (b) $\bar{H}_y^{(i)}(t_1 + t_2) \leq \bar{H}_y^{(i)}(t_1) \bar{H}_y^{(i)}(t_2)$, $i = 1, 2$, for all $t_1, t_2, y \geq 0$, then for any $k \geq 1$, $P(N_A(t_i; i, T) \leq n_i, i = 1, 2) \geq P(N_A(t_i; i, kT) \leq n_i, i = 1, 2)$, for all $t_i, n_i, i = 1, 2$.*

Finally, our last result gives us information regarding the weakest component (weakest in the sense that it is more likely to fail).

Theorem 3 *If X_1 is stochastically larger than X_2 (X_1 is said to be stochastically larger than X_2 if $\bar{F}_{X_1}(x) > \bar{F}_{X_2}(x)$ for all $x \geq 0$, see Shaked and Shanthikumar [6]), then (a) $P(N_1(t) \leq n) \geq P(N_2(t) \leq n)$ for all $n, t \geq 0$ and (b) $P(N_A(t; 1, T) \leq n) \geq P(N_A(t; 2, T) \leq n)$, for all $n, t \geq 0$.*

Intuitively speaking, Theorem 3 says that if component 1 has a larger survival function than component 2, then the number of times that component 1 fails is stochastically less than the number of times that component 2 fails under both MAR(T, T) and MRR.

Optimal Age Replacement under MAR(T, T)

In this section we determine an optimal replacement policy T^* under MAR(T, T) such that

$$C(T) = \frac{\text{the expected cost incurred in a cycle}}{\text{the expected length of a cycle}} \quad (5)$$

is minimized. Here a cycle is the time between two consecutive system failures. We note that $C(T)$

is being used as the criterion for evaluating the replacement policies.

Now, consider the following two cases.

Case I Series system (the system works if both components work). Let c_1 be the constant cost of replacement of one or both components when the system fails and let c_2 be the constant cost of a preventive replacement of both components at age T with $0 < c_2 < c_1 < \infty$. Then, equation (5) reduces to

$$C(T) = \frac{1}{\int_0^T \bar{F}(u, u) du} (c_1 - \beta \bar{F}(T, T)) \quad (6)$$

where $\beta = c_1 - c_2 > 0$. We can determine the optimal replacement policy T^* by minimizing the equation (6). The minimization procedure can be done by analytical or numerical methods. See Ebrahimi [5] for more details. In fact, one can show that T^* satisfies the following condition.

$$\frac{g(T)}{\bar{F}(T, T)} \int_0^T \bar{F}(u, u) du + \bar{F}(T, T) = \frac{c_1}{\beta} \quad (7)$$

where $g(T) = -\frac{d}{dt} \bar{F}(t, t)|_{t=T}$.

Case II Parallel System (the system works if at least one component works). Under this case equation (5) reduces to

$$C(T) = \frac{1}{\sum_{i=1}^2 \frac{\int_0^T \bar{F}_{X_i}(u) du}{1 - \bar{F}_{X_i}(T)} - \frac{\int_0^T \bar{F}(u, u) du}{1 - \bar{F}(T, T)}} \times \left(c_1 + c_2 \sum_{i=1}^2 \frac{\bar{F}_{X_i}(T)}{1 - \bar{F}_{X_i}(T)} - \frac{c_2 \bar{F}(T, T)}{1 - \bar{F}(T, T)} \right) \quad (8)$$

We may proceed as in Case 1 and determine the optimal policy T^* by minimizing $C(T)$ in the equation (8).

Applications

This section illustrates applications of our results that are obtained in the previous sections.

Bivariate Gumble Model

Consider X_1 and X_2 with the bivariate Gumble distribution

$$\bar{F}(x_1, x_2) = \exp[-\lambda_1 x_1 - \lambda_2 x_2 - \delta x_1 x_2], \\ x_1, x_2 \geq 0, \lambda_1, \lambda_2, \delta \geq 0 \quad (9)$$

See Gumble [7]. It is clear that $\bar{F}(x_1 + t_1, x_2 + t_2) \leq \bar{F}(x_1, x_2) \bar{F}(t_1, t_2)$. Also, $\bar{H}_y^{(1)}(x) = P(X_1 > x | X_2 > y) = \exp[-\lambda_1 x - \delta x y]$, $\bar{H}_y^{(2)}(x) = P(X_2 > x | X_1 > y) = \exp[-\lambda_2 y - \delta x y]$ and $\bar{H}_y^{(i)}(t_1 + t_2) \leq \bar{H}_y^{(i)}(t_1) \bar{H}_y^{(i)}(t_2)$, $i = 1, 2$, for $t_1, t_2 \geq 0$. Therefore, all the results in Theorems 1 and 2 are true for this family of distributions.

Marshall–Olkin Model

Consider X_1 and X_2 with the joint survival function of Marshall–Olkin bivariate exponential which is given by

$$\bar{F}(x_1, x_2) = \exp(-\lambda_1 x_1 - \lambda_2 x_2 - \delta \max(x_1, x_2)), \\ x_1, x_2 \geq 0, \lambda_1, \lambda_2 > 0 \text{ and } \delta \geq 0 \quad (10)$$

See Marshall and Olkin [8]. It is clear that

$$\bar{F}(x + t_1, x + t_2) \geq \bar{F}(x, x) \bar{F}(t_1, t_2) \quad (11)$$

Also, $\bar{H}_y^{(1)}(x) = \exp(-\lambda_1 x - \delta \max(x, y))$, $\bar{H}_y^{(2)}(x) = \exp(-\lambda_2 x - \delta \max(x, y))$ and $\bar{H}_y^{(i)}(t_1, t_2) \geq \bar{H}_y^{(i)}(t_1) \bar{H}_y^{(i)}(t_2)$, $i = 1, 2$, for $t_1, t_2 \geq 0$. Therefore all the results in Theorem 1 hold.

T^* for Bivariate Gumble and Marshall and Olkin Models

As an application of equation (6), consider the bivariate Gumble family of distributions which was described in the section titled “Bivariate Gumble Model”. For this case, equation (7) reduces to

$$\exp[-(\lambda_1 + \lambda_2)T - \delta T^2] + (\lambda_1 + \lambda_2 + 2\delta T) \\ \int_0^T \exp(-(\lambda_1 + \lambda_2) \\ \times u - \delta u^2) du = \frac{c_1}{\beta} \quad (12)$$

4 Multivariate Age and Multivariate Renewal Replacement

Now, suppose $c_1 = 2$, $c_2 = 1$ and $\lambda_1 = \lambda_2 = \delta = 1$. Then, we get T^* as approximately 0.27. Since $X_i, i = 1, 2$, has an exponential distribution with mean 1, it is clear that under the univariate age replacement policy $T^* = \infty$. Also under the Marshall and Olkin model for series system $T^* = \infty$. Intuitively speaking, this simply means that age replacement policy is not applicable in univariate case of exponential distribution and under the Marshall and Olkin model.

Concluding Remarks

In this article, we described several maintenance policies for multicomponent systems. Our policies are suitable for revealed failures of components, that is, failures that are detected as soon as they occur. There are also examples of units whose failures are not revealed unless some type of inspection is performed. Berrade [9] proposed a policy for unrevealed failures of components. While the results obtained in section titled "Contrast between MAR and MRR" are appropriate for the case in which components are replaced at the same time, $T_1 = T_2 = T$, it will be interesting to see if similar results are obtained when components are replaced at different times, $T_1 \neq T_2$.

Nonparametric Methods for Analysis of Repair Data

Introduction

Engineering systems and human systems are subject to failure. Rather than replacing the failed system by a new system, repair is implemented because substituting a new item for the failed item is impractical, not feasible, or too expensive. Thus we are led to the situation where a system, undergoing continued maintenance by having some type of repair applied after each failure, yields a data set consisting of the failure times and the type of repair administered at each failure.

A repair model is a stochastic formulation of the joint distribution of the failure times, or equivalently, the joint distribution of the interfailure times. We let $\{S_j\}$ denote the failure times of the system and $\{T_j\}$, the interfailure times, where $T_j = S_j - S_{j-1}$ and $S_0 \stackrel{\text{def}}{=} 0$. Let F be the distribution of the time to first failure of the system. It is of interest to estimate F (or equivalently the survival function $\bar{F} = 1 - F$) nonparametrically from the failure times and knowledge of the type of repairs made after each failure. Other parameters, such as the expected values of the interfailure times and other features of the repair process, can be expressed in terms of F . **Estimation** of F is not straightforward because data that arise from repair processes will typically have dependencies that are induced, for example, by the nature of the repair, other environmental factors, and the specification of the period of observation.

In the section titled “Repair Models” we discuss several of the prominent repair models in use. In the section titled “A General Repair Model” we address nonparametric estimation of F and describe a nonparametric asymptotic simultaneous confidence band for F . The section titled “Additional Nonparametric Methods” considers related nonparametric estimation and testing procedures for **repair data**.

Repair Models

In the *perfect repair model*, a failed system is replaced by a new one having the same stochastic properties

as the original. That is, $\{T_j\}$ are independent and identically distributed (i.i.d.) according to F . The imperfect repair model known as the **minimal repair model**, due to Ascher [1] (see **Imperfect Repair**), specifies that the repaired system has the same distribution as an operational new system with the age of the recently failed system. In symbols, the survival distribution function of the minimally repaired system is given by $\bar{F}_t$, where

$$\bar{F}_t(s) = \frac{1 - F(s + t)}{1 - F(t)}, \quad s > 0 \quad (1)$$

and t denotes the time of the previous failure. The Brown and Proschan (BP) [2] repair model is a generalization of the minimal repair model. The BP model is an imperfect repair model where at the time of each repair, a perfect repair is performed with probability p and a minimal repair is performed with probability $1 - p$. The Block, Borges, and Savits (BBS) [3] model generalizes the BP model by allowing the probability of a perfect repair to depend on the age of the failed system. Kijima [4] introduced two models, models I and II, that allow for repairs to be better than minimal but not as good as perfect repairs. In the Kijima models, the effective age to which the system is restored after repair depends on the effective age just before failure and the degree of repair random variables. Kijima’s models I and II are special cases of a repair model considered by Uematsu and Nishida [5]. Dorado, Hollander, and Sethuraman (DHS) [6] defined a general repair that contains many popular repair models and introduces many others. Because of its generality, we focus on it in the section titled “A General Repair Model”.

A General Repair Model

The DHS [6] model of imperfect repair is based on the family of survival distributions

$$\bar{F}_{a,\theta}(x) \stackrel{\text{def}}{=} \frac{\bar{F}(\theta x + a)}{\bar{F}(a)} \quad (2)$$

where θ is a positive parameter. This family enjoys a stochastic ordering property, namely, $\theta < \theta'$ implies $F_{a,\theta} \stackrel{\text{st}}{\geq} F_{a,\theta'}$ for each a . Thus lower values of θ imply longer remaining life. The DHS model is based on two sequences $\{A_j\}$, $\{\theta_j\}$ where the A ’s are

2 Nonparametric Methods for Analysis of Repair Data

called *effective ages* and the θ 's are known as *life supplements*. The A 's and θ 's are assumed to satisfy

$$\begin{aligned} A_1 &= 0, \theta_1 = 1, A_j \geq 0, \theta_j \in (0, 1] \text{ and} \\ A_j &\leq A_{j-1} + \theta_{j-1}T_{j-1}, j \geq 2 \end{aligned} \quad (3)$$

The DHS model is completely described by the joint distribution of the interfailure times given by

$$\begin{aligned} P(T_j \leq t | A_1, \dots, A_j, \theta_1, \dots, \theta_j, T_1, \dots, T_{j-1}) \\ = F_{A_j, \theta_j}(t) \end{aligned} \quad (4)$$

Note that, for $j \geq 1$, the effective age A_{j+1} of the system after the j th repair is less than the effective age $X_j \stackrel{\text{def}}{=} A_j + \theta_j T_j$ just before the j th failure, and because $\theta_j \leq 1$, X_j is less than the actual age S_j . The DHS model also encompasses an i.i.d. renewal model studied by Peña *et al.* [7] and Hollander and Peña [8].

All of the repair models mentioned in the section titled “Repair Models” are special cases of the DHS model. For example, setting $\theta_j = 1$, $A_j = S_{j-1}$ yields the minimal repair model. For the specifications of the A 's and θ 's that yield the other models of the section titled “Repair Models” and also many new repair models, see Dorado *et al.* [6].

DHS develops asymptotic inferential procedures for model (4) by invoking an analogy to a survival model with censored data. We refer the reader to Dorado *et al.* [6] for details and only summarize the results here.

DHS fixes a $T > 0$ and defines two processes $N(\cdot)$ and $Y(\cdot)$ by

$$N(t) = \sum_j I\{X_j \leq t, S_j \leq t\} \quad (5)$$

and

$$\begin{aligned} Y(t) = \sum_j I\{A_j < t \leq (X_j \wedge [A_j \\ + \theta_j(T - S_{j-1})])\} \end{aligned} \quad (6)$$

where $X_j = A_j + \theta_j T_j$ is the effective age just before the j th failure. DHS assumes that n independent copies of the processes N and Y are observed on

a finite interval. Let N_n and Y_n denote the sum of the n independent copies of N and Y , respectively. Let Λ denote the cumulative hazard function of F . The Nelson–Aalen estimator of Λ of is

$$\hat{\Lambda}_n(t) = \int_0^t \frac{J_n}{Y_n} dN_n \quad (7)$$

where $J_n(t) = I(Y_n(t) > 0)$. The DHS estimator of $\bar{F}$ is

$$\hat{\bar{F}}_n(t) = \prod_{s \leq t} (1 - d\hat{\Lambda}(s)) \quad (8)$$

where $\prod_{s \leq t} (1 - d\hat{\Lambda}(s))$ denotes the product integral (see Gill and Johansen [9]). The estimate $\hat{\bar{F}}_n(t)$ can be shown to be the solution of the Volterra integral equation

$$\hat{\bar{F}}_n(t) = \int_0^t (1 - \hat{\bar{F}}_n(s-)) d\hat{\Lambda}_n(s) \quad (9)$$

DHS obtained weak convergence results for $\hat{\bar{F}}_n(t)$ and also derived a simultaneous confidence band for $\bar{F}$. For $t \in [0, T]$, let $L_n = I(\bar{F}_n(t) < 1)$ and set

$$\begin{aligned} \hat{C}_n(t) &= \int_0^t \frac{J_n L_n}{(Y_n/n)(1 - \hat{\bar{F}}_n)} d\hat{\bar{F}}_n, \\ \hat{K}_n(t) &= \frac{\hat{C}_n(t)}{1 + \hat{C}_n(t)} \end{aligned} \quad (10)$$

For t such $\hat{\bar{F}}_n(t) = 1$, set $\hat{K}_n(t) = 1$. A nonparametric asymptotic simultaneous confidence band for $\bar{F}$ with confidence coefficient at least $100(1 - \alpha)$ is

$$\hat{\bar{F}}_n \pm n^{-1/2} \frac{\lambda_\alpha (1 - \hat{\bar{F}}_n)}{(1 - \hat{K}_n)} \quad (11)$$

where λ_α is such that

$$P\left(\sup_{t \in [0, 1]} |B^0(t)| \leq \lambda_\alpha\right) = 1 - \alpha \quad (12)$$

and B^0 denotes a Brownian bridge on $[0, 1]$.

The following formulas are computational simplifications. Let $X_{(1)}, X_{(2)}, \dots, X_{(r)}$ be the distinct

ordered values of the X 's whose corresponding failure times are within $[0, T]$. Let δ_j be the number of observations with value $X_{(j)}$. Then

$$\hat{F}_n(t) = \prod_{X_{(j)} \leq t} \left(1 - \frac{\delta_j}{Y_n(X_{(j)})}\right) \quad (13)$$

and

$$\hat{C}_n(t) = n \sum_{X_{(j)} \leq t} \frac{\hat{F}_n(X_{(j)}) - \hat{F}_n(X_{(j-1)})}{Y_n(X_{(j)})(1 - \hat{F}_n(X_{(j)}))} \quad (14)$$

Some data sets will lead to $\hat{F}_n(t_0) = 1$ for some $0 < t_0 < T$. For such data sets, the band obtained is a confidence band only on the interval $(0, \sigma)$ where $\sigma = \inf\{t \in [0, T] : \hat{F}_n(t) = 1\}$.

The restriction $\theta_j \in (0, 1]$ imposed by DHS (see equation (3)) does not allow for destructive repair. Last and Szekli (LS) [10] do permit deterioration due to repair by extending Kijima's model II. LS show that their repair model contains many models proposed in the literature including those of Stadjé and Zuckerman [11] and Baxter *et al.* [12].

Additional Nonparametric Methods

Let P denote the probability measure associated with the life distribution F . The restriction P_A of a probability measure P to a set A is defined by

$$P_A(B) = \frac{P(A \cap B)}{P(A)} \text{ if } P(A) > 0 \quad (15)$$

To complete the formal definition when $P(A) = 0$, define $P_A = \mu$ where μ is some conveniently chosen probability measure. Another generalization of the BBS model can be formed by postulating that T_1 has distribution P and that for $n \geq 1$, the distribution of T_{n+1} , given the failure times $T_1, \dots, T_n$ and other environmental factors $E_1, \dots, E_n$ observed at those failure times, is

$$P(T_{n+1} \in B) = P_{A_n}(B) \quad (16)$$

where A_n is a set that depends (measurably) on $T_1, \dots, T_n, E_1, \dots, E_n$. Appropriate choices of the restriction sets $A_1, A_2, \dots$ generate different repair

models. Bayesian nonparametrics for repair model (16) puts a prior distribution on P . For integrated squared-error loss, the Bayes estimator of P is the expected value of the posterior distribution of P , given the data. Sethuraman and Hollander (SH) [13, 14] introduced a new class of priors for Bayesian nonparametrics called *partition-based (PB) priors* and a subclass called *partition-based Dirichlet (PBD) priors*. They utilize these priors to show how to obtain posterior distributions under such priors, and obtain Bayes estimators of F in model (16). When specialized to the BBS model, the SH nonparametric Bayes estimators are competitors to the Whitaker and Samaniego (WS) [15] nonparametric estimator of F (see **Imperfect Repair**).

Kvam *et al.* [16] use isotonic regression techniques to find maximum-likelihood estimators of F and its failure rate when F is known to have an increasing failure rate. Suppose that we have data from a BBS repair consisting of n systems, each observed till the time of a perfect repair. Presnell, Hollander and Sethuraman (PHS) [17] proposed **non-parametric tests** of the minimal repair assumption in the BBS model. Their Mann–Whitney–Wilcoxon-type statistic is of the form $\int \hat{F}_e d\hat{F}$ where $\hat{F}$ is the WS estimator and $\hat{F}_e$ is the empirical distribution based on the initial failure times of n systems. They also studied a Kolmogorov–Smirnov (KS)-type test based on the maximum absolute difference between $\hat{F}$ and $\hat{F}_e$. We briefly describe the KS-type test. A consistent estimator of F is provided by $\hat{F}_e$ and, under the BBS model, $\hat{F}$ also consistently estimates F . If, however, the minimal repair assumption does not hold, $\hat{F}$ may likely diverge from F . Let $\hat{H}$ be the empirical distribution of the time to perfect repair of the n systems. Let

$$D(t) = \int_0^t \frac{dF(s)}{(1 - H(s))(1 - F(s))}$$

$$\hat{D}(t) = \int_0^t \frac{d\hat{F}(s)}{(1 - \hat{H}(s))(1 - \hat{F}(s))}$$

$$L(t) = \frac{1}{(1 - F(t))} - 1 - D(t)$$

$$\hat{L}(t) = \frac{1}{(1 - \hat{F}(t))} - 1 - \hat{D}(t)$$

$$G = \frac{L}{1+L}, \text{ and } \hat{G} = \frac{\hat{L}}{1+\hat{L}} \quad (17)$$

Corollary 2.2 of Presnell *et al.* [17] shows that a test of the minimal repair assumption can be performed by referring

$$S_\tau = \sup_{0 \leq t \leq \tau} \sqrt{n} \frac{(1 - \hat{G}(t))}{(1 - \hat{F}(t))} |\hat{F}(t) - \hat{F}_e(t)| \quad (18)$$

to a table of the supremum of the absolute value of the Brownian bridge over the interval $[0, \hat{G}(\tau)]$ (*cf.* Hall and Wellner [18] and Koziol and Byar [19]).

Hollander *et al.* [20] considered the case where two BBS processes are observed, each until its first perfect repair. They test $H_0: F_1 = F_2$, where F_i is the distribution of the time to first failure for process i , $i = 1, 2$. Their test statistic is $W = \int_0^\infty \hat{F}_1 d\hat{F}_2$ where $\hat{F}_i$ is the WS estimator for the i th process. For the BBS model, Augustin and Peña [21, 22] derived goodness-of-fit tests of $H_0: \Lambda = \Lambda_0$ where Λ_0 is completely specified. Augustin and Peña [23] developed tests for the composite case where the functional form of the failure rate $\lambda_0(\cdot, \xi)$ is known except for the value of ξ . Peña and Hollander (PH) [24] consider a general model for recurrent events that allows for interventions and incorporates covariates. Their general model contains the DHS and LS models as special cases. González *et al.* [25] apply the PH model for modeling intervention effects after cancer relapses.

System Availability

Overview

All mechanical, electrical, nuclear power generation, propulsion, weapons, computer and data storage (both hard and software), communications, and biological/medical systems, and many combinations thereof that are designed, manufactured, tested, operated, and maintained with human skills, engineering, and scientific knowledge, *are subject to failure*. This means that they become unable to perform the intended design function, or mission. *Reliability* is a measure of the propensity of component, subsystem, or system (of systems) to satisfactorily perform a required designed performance function on, say, a military or homeland security mission. This includes effectively and promptly responding to a natural disaster such as a hurricane (Katrina), tornado, or earthquake. During the period of inability to perform, the item is said to be *not available* or *unavailable*. Often this propensity is quantified as a (conditional) probability, where the conditions include stressful aspects of the operational environment and usage. Note that it is not customary to include *vulnerability* to opponent action in measures of military or security system reliability. Many, even most, failed systems are subject to failure correction or rectification, which often requires a nonnegligible total *downtime*, during which time interval they are completely or partially unavailable. Thus an initial informal definition of *availability* can be an estimated probability that, at the moment of demand/need for a system's performance, it will furnish that service, and not be in the process of waiting or being rectified/repaired/replaced. Note that field support of system availability and capability to accomplish a mission profile depends upon *sustainment resources*: personnel, logistics/spare parts, tow vehicles, and so on. These must also be available when needed.

It is often true that the failure propensity measure, or *hazard*, or *hazard rate*, of a component, subsystem, or system eventually increases with time or intensity of usage and "wear" or "age" after being fielded. Typically, a new or modified/upgraded system is tested so as to identify and remove or reduce the effect of *design defects* or *failure modes*; during the early testing period every attempt is made to induce the activation, thus exposure of, *design defects* or *failure*

modes, i.e., to *stimulate* occurrences of failures and remove their causes; see [1]. Some faults inevitably remain, and can be found during routine scheduled maintenance. However, most such maintenance can be unnecessary (time-scheduled maintenance is costly in time and resources, and may well find nothing). It is currently thought to be desirable and increasingly technically feasible, to identify and automatically track *system health* changes: failure-preceding or prognostic events (excess heat, undue vibration, wear of say tire treads, tire, engine oil condition, etc.) that can signal an incipient failure and thereby suggest needed system design or operational changes before total, possibly catastrophic, failure can occur. This procedure is known as *condition-based maintenance* (CBM), and makes use of currently available automated embedded sensors; hence CBM+. However, the CBM+ subsystem is itself subject to malfunction and failure, so false-positive and false-negative diagnoses must be anticipated and made rare in order for overall gains to be made. Thus the reliability/availability of CBM+ must itself be considered as part of the total system package.

Accelerated testing procedures are often used at an early (developmental) testing stage; see [2]. During the testing phase, both developmental and operational, it is intended, likely, and desirable, to *find design faults and, desirably, "fix" them*, so that they will not occur/activate and cause mission-abortive events under active field conditions. It is the usual objective to test and "fix" until times between failures during testing become a stable-in-time random process, often represented by a *time-between-successive-failures distribution*, with the further assumption that the times between failures are statistically independent (*independent identically distributed random variables*, i.i.d.r.v.'s); see [2], and several computer packages, such as ReliaSoft (www.reliasoft.com).

However, initial tests of a newly designed system typically reveal "infant failures" that should be removed before any approximate stability of times between failures occurs. Such removal is referred to as *reliability growth*, and it has been modeled and analyzed extensively, e.g. by Crow [3, 4], e.g. in the software package ReliaSoft; see also [1] for discussion of testing for growth using a sequential (run of successes) stopping rule; such testing is made more complex if the system performance is in sequential stages; failure of an early stage may mask the exposure of later stages, thus requiring

longer tests so as to explore all stages for faults. After (*if*) there is evidence of failure-time stochastic stability it is meaningful to speak of the *mean (operating) time between failures*; this is often specified as a reliability metric, but an estimate of the probability of mission success is usually more relevant, certainly if the item is one-shot, or is usually quiescent in performance: a piece of ammunition or a communication system for emergencies. Caution is required: justification for such a stable failure-time distribution must depend on actual data monitoring, and the currently appropriate particular distributional form (model) may well depend on environmental conditions, including maintenance skill, and usage and environment; e.g., operating times between successive failures for a particular equipment (helicopter) in the Arctic can be expected to differ from those operating under tropical, sandy, desert conditions.

Upon failure, some (but not all, e.g., expendable missiles and ammunition) system components are repaired; this requires maintenance facilities and personnel, and logistics (spare parts); the system may then be again capable of performing the functions it was designed for. Repair or replacement is intended to restore original capability, or possibly upgrade (or in fact unintentionally and occasionally *downgrade*) system function. **Preventive maintenance** (PM), based on the observed or inferred/sensed physical condition of the system, may be used to ward off catastrophic failures. As stated earlier, current attention is being focused on automated information-system-supported *CBM+* (alternatively, integrated vehicle health management, *IVHM*). Such subsystems continuously monitor the “health condition” of other subsystems and provide warning of imminent malfunction/failure. If successful, such a capability should allow more operative mission hours and shorter and less time-consuming and costly repairs. Success depends upon the trustworthiness of the *CBM+/IVHM* systems available; see [5–7].

This chapter considers that times or events between such system failures (during functional usage) are punctuated by periods of “downtime”, during which the system (copy or version thereof) is (a) awaiting maintenance, which may include moving, or being moved, to a repair facility, and awaiting the arrival of parts, instrumentation, and personnel; (b) undergoing diagnosis of faults and subsequent maintenance actions; or (c) awaiting

further operational assignment (in idle standby). Items may fail or degrade during such waiting/idle times, and so preliminary tests may be performed prior to mission assignment: premission testing is often done, especially with aircraft and other platforms. This permits the detection of **imperfect repair** before the mission actually is in progress.

The (classical) system *operational availability* (*Ao*) *parameter* is a measure of the capability of a system to *begin* to perform the designed-for function or mission *on immediate random demand*. Nominally, this would imply that the system is in state (c) above, but too long a sojourn of idleness (in “cold standby”), in a hostile environment can induce *startup unavailability*. *Mission availability*, measuring the capability of a system to perform its function from demand for service until mission termination is usually of far more operational significance than simple *Ao*. The latter is too often treated – inappropriately – as “the long-run fraction of time” (or “constant probability”) that a component or system is “up” or completely mission capable at the time of demand for operation. In reality such a constant value may not prevail; “the” value of *Ao* may well change with time and usage, including maintenance variation between individual copies of a system design. Often no account is taken of system age or condition, or the variable mission environment that may affect it. Further, a system’s availability may be partial: e.g., a multiengine vehicle can still function if degraded by the loss of one out of several engines. However, loss of an engine or, one of several sensors, or a communication link sometimes allows a modified or limited version of the intended mission to proceed until a replacement is furnished. Consequently, availability need not be a binary instantaneous concept.

The object of this chapter is to describe methods in use for describing, measuring, testing, and improving *availability* and to provide cautionary comments similar to those above.

Component and System Operational Classification

Engineered systems of all types are composed of numbers of components (“parts”), subsystems, and entire systems designed to perform cooperative functions. Modern warfare has been said to be conducted by “systems of systems”. Such systems usually operate efficiently and effectively according to correct

design, manufacture, and usage. They inevitably fail or degrade with age and stress; some failure modes are mission and even life threatening, and can occur with little warning. Hence, condition-based monitoring condition-based maintenance (CBM) and PM are required and invoked; time spent in such situations makes the entity temporarily mission unavailable, but can provide greater overall net system mission availability.

Systems, and especially subsystems and components, can be roughly categorized as

- *One shot/disposable* (e.g., fuel, ammunition, missiles, or mines, electronic components, such as computer chips or screens, remote vulnerable sensors, etc.) and/or
- *Repairable (segmentally)/replaceable* (e.g., failure-prone engines and control devices, vehicle chassis, computer hardware, elements of communication networks, etc.) An injured or wounded human can sometimes be included in this category, as being part of an entire system.

In many cases, a failed repairable system becomes less susceptible to repair if too much time elapses, so the *particular item's* availability terminates, but its function is performed by a replacement or substitute; the latter can be a redesigned upgrade; see [1]. Further, the pattern of component/system usage can vary: many items such as some sensors and alarm systems and engines and generators are normally running or “hot” during a mission, so if failure occurs or becomes imminent, symptoms are evident. Others are normally inactive or “cold”, such as an idle aircraft parked on a flight deck or a rescue vehicle.

Many systems are made up of complex assemblies or combinations of one shot/disposable and repairable/replaceable subsystems: a vehicle or platform burns fuel and may fire ammunition, both disposable, but its chassis, propulsion, and steering and sensors and communications are very often repairable/replaceable. Many vehicles operate in groups: convoys of trucks or small boats, task groups, aircraft squadrons, and so on; here the mission may involve all elements of the group, so the timely availability of such a subforce at a particular site can be spoiled if just one of the member elements fails: the entire system may become mission incapable or unavailable if one or more

of such elements fails or is damaged by opponent action (when in military or homeland protection application), or by owner/user mishandling. The tendency for this to occur is enhanced when hostilities occur, and when the sustainment/support forces and logistics are overwhelmed and themselves unavailable.

Modeling Availability

System availability has been characterized probabilistically or stochastically for many years; an initial classic is [8], but aspects of repairable system availability go far back to Erlang, Khinchine, and to Palm in the 1930s and a further few decades, well summarized in [9] as the “repairman problem” or service system. See also [10–11] on survival analysis, essentially summarizing biological (e.g., animal, human “reliability”); failure prone but **repairable systems** resemble biological epidemics: failures of subsystems can stress, or infect, other subsystems that in turn can cause total system collapse if not quickly isolated and mitigated.

The simplest analytical model for a failure prone but repairable system is the alternating renewal process (see, however, practical cautions in the section titled “Overview”). Letting a sequence of uptimes, $\{U_i\}$, and a sequence of downtimes, $\{D_i\}$, be independent sequences of independent random variables with marginal distributions $F_U(u; \underline{\theta})$ and $G_D(v; \underline{\varphi})$, respectively, and $\underline{\theta}$ and $\underline{\varphi}$ representing parameters; then if $A(t)$ is the availability at time t , given that the subsystem starts at the beginning of an up period, U_1 , say, we have the backward recurrence renewal equation

$$A(t) = P\{U_1 > t\} + \int_0^t P\{U_1 + D_1 \in dx\} A(t - x) \quad (1)$$

which can be solved numerically or in terms of Laplace–Stieltjes transforms. Basic renewal theory asymptotics, [12, Chapter 11], shows that if $E[U]$ and $E[D]$ exist/are finite then

$$\lim_{t \rightarrow \infty} A(t) = E[U]/(E[U] + E[D]) = A_o \quad (2)$$

the popular (often misused) operational availability. In cases in which the system must function throughout a mission of length M a more informative measure is mission availability

$$A_m = A_o \frac{P\{U > M\}}{E[U]} \quad (3)$$

an asymptotic renewal theory result.

Complex systems, starting with series/tandem configurations, and extending to series/parallel/redundant combinations can be mathematically analyzed under the initially stated independence assumptions, and with these progressively relaxed.

Statistical Inference on Availability

If the simple assumption of mutually independent sequences of independent identically distributed (i.i.d.) uptime r.v.'s, $\{U_i\}$ and likewise i.i.d. downtimes, $\{D_i\}$ is (provisionally) acceptable then alternating renewal theory shows that the long-run *point availability* is given by $A_o = E[U]/(E[U] + E[D])$, provided expectations exist. A natural estimate of A_o , $\hat{A}_o = \bar{u}/(\bar{u} + \bar{d})$, where $\bar{u}$ and $\bar{d}$ are the sample averages of up and down realizations; assume no censoring; Gaver and Chu assess **confidence intervals** for A_o using jackknifing [13], wherein the logit transform of $\hat{A}_o$ is recomputed, omitting pairs of observations successively. The method can be applied with successfully to various redundant systems and several plausible distributional forms. An alternative would be the **bootstrap** (see [14]). A sensible (semi) nonparametric approach is the nonparametric bootstrap: resample from the empirical distributions of up- and downtimes, provided that preliminary examination of the data does not wildly contradict i.i.d. assumptions; see [15]. In many applied situations, data may be insufficient to validate (or invalidate) such an assumption conclusively. It may well be wise to adaptively smooth up- and downtime means and employ these in the $\hat{A}_o$ formula. Details are available from the references.

Conclusion

Many more, and more complex, results are available from the references. For an excellent general overview see [16].

Multivariate Imperfect Repair Models

Introduction

In the study of **maintenance policies** for simple **repairable systems**, i.e. a one-component repairable system with a single repairman, a common assumption is that the system after repair is “as good as new”. This constitutes a perfect repair model. However, because of aging and cumulative wear effects, it is known in practice that repair of a failed system may not yield a functioning system that is as good as new. Barlow and Hunter [1] presented a **minimal repair** model in which repair does not change the age of the system. Brown and Proschan [2] and Berg and Cleroux [3] examined a maintenance action, called the **imperfect repair model**, in which a system is repaired at failure, with probability α , and that it is returned to the as good as new state (perfect repair) and with probability $(1 - \alpha)$ that it is returned to the functioning state, but is only as good as a system of its age at failure (minimal repair). This model has been generalized by Block *et al.* [4] to the case in which α depends on the age of the system at failure. Much work has been performed in this direction since then. See for example, Balaban and Singpurwalla [5], Uematsu and Nishida [6], Langberg [7], Kijima [8], Ebrahimi [9], Last and Szekli [10], Li and Shaked [11], Belzunce and Semeraro [12], Wang and Zhang [13], and many references cited there.

As systems become more complicated and require new technologies and methodologies, more sophisticated repair policies are needed. More specifically, it is quite common to find systems consisting of k components which are related. In such cases, a legitimate question is how to generalize an imperfect repair model to a system with several components. This article deals with multivariate versions of imperfect repair models that may be used for exploring effects of imperfect repairs of some components on the residual lives of components that are still functioning. Throughout this article “increasing” means “nondecreasing” and “decreasing” means “nonincreasing”.

Models, Notations, and Terminology

Consider a system consisting of k components that are related. Let $T = (T_1, \dots, T_k)$ be the vector of lifetimes of components when the components do not undergo any kind of repair. Also, let $T^* = (T_1^*, \dots, T_k^*)$ be the waiting times of components until the first perfect repair starting with new components when they are subjected to imperfect repair. Suppose $\bar{F}$ and $\bar{G}$ are joint survival functions of T and T^* , respectively. That is, $\bar{F}(t_1, \dots, t_k) = P(T_1 > t_1, \dots, T_k > t_k)$ and $\bar{G}(t_1, \dots, t_k) = P(T_1^* > t_1, \dots, T_k^* > t_k)$. We use F and G for joint distribution functions of T and T^* , respectively. For $k = 1$, Brown and Proschan [2] observed that if $\lambda(t) = \frac{f(t)}{\bar{F}(t)}$ is the original hazard function of T_1 , then the resulting hazard function of T_1^* , $\lambda^*(t) = \frac{g(t)}{\bar{G}(t)}$ is $\lambda^*(t) = \alpha\lambda(t)$. Hence $\bar{G}(t) = (\bar{F}(t))^\alpha$. Here f and g are the probability density functions of T_1 and T_1^* , respectively.

Consider models in which, if at some time t_0 , component i_0 fails and is imperfectly repaired, then i_0 is as good as an identical functioning component of age t_0 (minimal repair), and the remaining functioning components “do not know” about the component i_0 ’s failure and imperfect repair. Specifically, suppose that components $j_1, \dots, j_\ell$ have been perfectly repaired at times $t_{j_1}, \dots, t_{j_\ell}$ respectively, and $t_{j_i} < t_0$, for $i = 1, \dots, \ell$. Also, components $i_1, \dots, i_m$ are still functioning at time t_0 and the component i_0 has just been imperfectly repaired. Note that $\{j_1, \dots, j_\ell, i_1, \dots, i_m, i_0\} = \{1, \dots, k\}$. Then, it is clear that the distribution of the times to next failure of components $i_0, i_1, \dots, i_m$ is

$$P\left\{T_{i_0} \leq t_{i_0}, T_{i_1} \leq t_{i_1}, \dots, T_{i_m} \leq t_{i_m} | T_{i_0} > t_0, T_{i_1} > t_0, \dots, T_{i_m} > t_0; T_{j_1} = t_{j_1}, \dots, T_{j_\ell} = t_{j_\ell}\right\} \quad (1)$$

On the other hand, if the component i_0 at time t_0 has been perfectly repaired, then

$$P\left\{T_{i_1} \leq t_{i_1}, \dots, T_{i_m} \leq t_{i_m} | T_{i_1} > t_0, \dots, T_{i_m} > t_0; T_{j_1} = t_{j_1}, \dots, T_{j_\ell} = t_{j_\ell}; T_{i_0} = t_0\right\} \quad (2)$$

Assuming that $\bar{F}(t_1, \dots, t_k)$ is absolutely continuous, i.e., no more than one component can fail at a

2 Multivariate Imperfect Repair Models

time, below we describe two multivariate imperfect repair models:

Model 1 k components start to function at (the same) time zero. Upon failure, a component undergoes a repair. With probability α the repair is unsuccessful and the component is scrapped (perfect repair). With probability $(1 - \alpha)$, the repair is imperfect repair. It is clear that the joint distribution of the times to next failure of the functioning components after an imperfect (perfect) repair is given by equations (1) and (2).

Model 2 k components start to function at time zero. Upon failure, a component undergoes a repair. If n components ($n = 0, 1, \dots, k - 1$) have already been perfectly repaired, with probability α_{n+1} the repair of the component is perfect and with probability $1 - \alpha_{n+1}$ the repair is imperfect repair. It is clear that the joint distribution of the times to next failure of functioning components after an imperfect (perfect) repair is given by equations (1) and (2). For more details about these models, see Shaked and Shanthikumar [14] and Natvig [15].

If we consider the case in which there is a positive probability that at least two of the original components can fail at the same time, that is, $\bar{F}(t_1, \dots, t_k)$ has singularities on sets of the form $\{(t_1, \dots, t_k); t_{i_1} = \dots = t_{i_\ell}\}$ for some $1 \leq i_1 < i_2 < \dots < i_\ell \leq k$. Then, the following two interpretations of model 1 are possible.

Interpretation 1 If two or more components fail at the same time, all the failed components are scrapped with probability α or all the failed components are minimally repaired with probability $(1 - \alpha)$.

Interpretation 2 If two or more components fail at the same time, then each of them, independently of the others, is either successfully minimally repaired with probability $(1 - \alpha)$ or scrapped with probability α .

The next model gives a very general repair policy when $\bar{F}(t_1, \dots, t_k)$ has singularities. To describe this model, let S denote the set of vectors $(s_1, s_2, \dots, s_k)$, where $s_j = 0$ or 1 for $j = 1, \dots, k$. Here $s_j = 0$ means that the component j is minimally repaired and $s_j = 1$ means that the component j is scrapped.

Model 3 k components start at time zero. Upon failure, a component undergoes a repair. There are several sources which cause the failures of components $1, 2, \dots$, and k . Source $\ell(j)$ causes the failure of component j ; with probability $\alpha(j)$ the repair

of this component is perfect and with probability $(1 - \alpha(j))$ the repair is imperfect, $j = 1, \dots, k$. For given i and $j, i \neq j, i, j = 1, \dots, k$, source $\ell(i, j)$ causes the failures of both components i and j , with probability $\alpha(i, j; s_i, s_j)$ the component i (component j) is minimally repaired if $s_i = 0$ ($s_j = 0$). Otherwise it is scrapped. For example, if $s_i = s_j = 1$, then $\alpha(i, j, 0, 0)$ stands for the probability that both components are minimally repaired. If $s_i = 0, s_j = 1$, then $\alpha(i, j, 1, 0)$ stands for the probability that component j is scrapped and component i is minimally repaired. Here $\alpha(i, j, 1, 1) + \alpha(i, j, 0, 0) + \alpha(i, j, 1, 0) + \alpha(i, j, 0, 1) = 1$. For a given $i, j, m; i \neq j \neq m, i, j, m = 1, \dots, k$, the source $\ell(i, j, m)$ causes the failure of three components i, j , and m ; with probability $\alpha(i, j, m; s_i, s_j, s_m)$ either one or two or three are minimally repaired depending on whether s_i, s_j , or s_m are zero or one. Again here, $\sum_{s_i} \sum_{s_j} \sum_{s_m} \alpha(i, j, m, s_i, s_j, s_m) = 1$. Continuing this, suppose source $\ell(1, 1, \dots, 1)$ causes the failures of all k components. Then $\alpha(1, 1, \dots, 1, s_1, \dots, s_k)$ is the probability that either one, two, ... or all k components are minimally repaired depending on whether $s_1, s_2, \dots$, or s_k are zero or one. Note that $\sum_S \alpha(1, 1, \dots, 1, s_1, s_2, \dots, s_k) = 1$. It is clear that $k = 2$, then $\alpha(1)$ and $\alpha(2)$ are the probabilities of perfect repairs of components 1 and 2, respectively. Also $\alpha(1, 1, 0, 0)$, $\alpha(1, 1, 0, 1)$, $\alpha(1, 1, 1, 0)$, and $\alpha(1, 1, 1, 1)$ are the probabilities that both components are minimally repaired, component 1 is minimally repaired, component 2 is minimally repaired, and both components are scrapped. This coincides with the model (3.5) of Shen and Griffith [16].

Main Results

In this section, we obtain the distribution of G in terms of F . We treat the bivariate case ($k = 2$) to keep the notations manageable. The results, however, can be easily extended to the k -dimensional case.

The following theorem gives the distribution of G in terms of F under Models 1 and 2. See Shaked and Shanthikumar [14] for more details.

Theorem 1 Suppose that (T_1, T_2) has the joint density function f and (T_1^*, T_2^*) has the joint density function g :

(a) Under Model 1,

$$\begin{aligned}
 g(t_1, t_2) &= f(t_1, t_2) \alpha^2 (\bar{F}(t_1, t_2))^{\alpha-1} \\
 &\times \left[\frac{\bar{F}_2(t_2|t_1)}{\bar{F}_2(t_1|t_1)} \right]^{\alpha-1} \text{ if } 0 \leq t_1 \leq t_2 \quad (3) \\
 &= f(t_1, t_2) \alpha^2 (\bar{F}(t_1, t_2))^{\alpha-1} \\
 &\times \left[\frac{\bar{F}_1(t_1|t_2)}{\bar{F}_1(t_2|t_2)} \right]^{\alpha-1} \text{ if } 0 \leq t_2 \leq t_1 \quad (4)
 \end{aligned}$$

where $\bar{F}_1(x|y) = P(T_1 > x | T_2 = y)$ and $\bar{F}_2(x|y) = P(T_2 > x | T_1 = y)$.

(b) Under Model 2,

$$\begin{aligned}
 g(t_1, t_2) &= f(t_1, t_2) \alpha_1 \alpha_2 (\bar{F}(t_1, t_2))^{\alpha_1-1} \\
 &\times \left[\frac{\bar{F}_2(t_2|t_1)}{\bar{F}_2(t_1|t_1)} \right]^{\alpha_2-1} \text{ if } 0 \leq t_1 \leq t_2 \\
 &= f(t_1, t_2) \alpha_1 \alpha_2 (\bar{F}(t_1, t_2))^{\alpha_1-1} \\
 &\times \left[\frac{\bar{F}_1(t_1|t_2)}{\bar{F}_1(t_2|t_2)} \right]^{\alpha_2-1} \text{ if } 0 \leq t_2 \leq t_1 \quad (5)
 \end{aligned}$$

From Theorem 1, under Model 2, one can easily show that

$$\begin{aligned}
 P(T_1^* \leq T_2^*) &= \int_0^\infty \alpha_1 (\bar{F}(t, t))^{\alpha_1-1} \\
 &\times \bar{F}_2(t|t) f_1(t) dt \quad (6)
 \end{aligned}$$

where f_1 is the marginal density of T_1 . Also, the marginal density function of T_1^* is

$$\begin{aligned}
 g_1(t) &= \alpha_1 (\bar{F}(t, t))^{\alpha_1-1} f_1(t) \bar{F}_2(t|t) \\
 &+ \alpha_1 \alpha_2 \int_0^t \left\{ f(t, x) (\bar{F}(x, x))^{\alpha_1-1} \right. \\
 &\times \left. \left[\frac{\bar{F}_1(t|x)}{\bar{F}_1(x|x)} \right]^{\alpha_2-1} \right\} dx \quad (7)
 \end{aligned}$$

The density of T_2^* can be written in a similar manner. Suppose that

$$\bar{F}(t_1, t_2) = P(U_1 > t_1, U_2 > t_2,$$

$$\begin{aligned}
 U_{12} &> \max(t_1, t_2)) \\
 &= \bar{F}_1(t_1) \bar{F}_2(t_2) \bar{F}_{12}(\max(t_1, t_2)) \quad (8)
 \end{aligned}$$

where U_1, U_2 , and U_{12} are independent random variables having cumulative distribution functions F_1, F_2 , and F_{12} , respectively.

Given equation (8), under Model 3, the following theorem gives the distribution of G in terms of F_1, F_2 , and F_{12} . See Shen and Griffith [16] for more details.

Theorem 2 Under Model 3,

$$\begin{aligned}
 \bar{G}(t_1, t_2) &= (\bar{F}_1(t_1))^{\alpha(1)} (\bar{F}_{12}(\max(t_1, t_2)))^{\alpha(1,1,0)} \\
 &\times (\bar{F}_2(t_2))^{\alpha(2)} (\bar{F}_{12}(\max(t_1, t_2)))^{\alpha(1,1,0,1)} \\
 &\times (\bar{F}_{12}(\max(t_1, t_2)))^{\alpha(1,1,1,1)} \quad (9)
 \end{aligned}$$

Examples

In this section, we apply our results to two families of distributions.

Marshall–Olkin Distribution

The random vector (T_1, T_2) is said to have the bivariate Marshall–Olkin exponential distribution, see Marshall and Olkin [17], if

$$\begin{aligned}
 \bar{F}(t_1, t_2) &= \exp(-\lambda_1 t_1 - \lambda_2 t_2 - \delta \max(t_1, t_2)), \\
 t_1, t_2 &\geq 0, \lambda_1, \lambda_2 > 0, \delta \geq 0 \quad (10)
 \end{aligned}$$

Given that $\alpha(1) = \alpha(2) = \frac{1}{2}$ and $\alpha(1, 1, 1, 0) = \alpha(1, 1, 1, 1) = \alpha(1, 1, 0, 1) = \alpha(1, 1, 0, 0) = \frac{1}{4}$. From Theorem 2,

$$\begin{aligned}
 \bar{G}(t_1, t_2) &= \exp \left(-\frac{\lambda_1}{2} t_1 - \frac{\lambda_2}{2} t_2 \right. \\
 &\quad \left. - \frac{3}{4} \delta \max(t_1, t_2) \right) \quad (11)
 \end{aligned}$$

4 Multivariate Imperfect Repair Models

Bivariate Gumble Model

Consider T_1 and T_2 with the bivariate Gumble distribution, see Gumble [18],

$$\begin{aligned}\bar{F}(t_1, t_2) &= \exp(-\lambda_1 t_1 - \lambda_2 t_2 - \delta t_1 t_2), t_1, t_2 \geq 0, \\ \lambda_1, \lambda_2 &> 0, \delta \geq 0\end{aligned}\quad (12)$$

It is clear that

$$\begin{aligned}f(t_1, t_2) &= [(\lambda_1 + \delta t_2)(\lambda_2 + \delta t_1) - \delta] \\ &\quad \times \exp(-\lambda_1 t_1 - \lambda_2 t_2 - \delta t_1 t_2)\end{aligned}\quad (13)$$

$$\begin{aligned}\bar{F}_2(x|y) &= P(T_2 > x | T_1 = y) \\ &= \frac{(\lambda_1 + \delta x)}{\lambda_1} \exp(-\lambda_2 x - \delta x y)\end{aligned}\quad (14)$$

and

$$\begin{aligned}\bar{F}_1(x|y) &= P(T_1 > x | T_2 = y) \\ &= \frac{(\lambda_2 + \delta x)}{\lambda_2} \exp(-\lambda_1 x - \delta x y)\end{aligned}\quad (15)$$

Now, suppose that $\alpha_1 = \alpha_2 = 1/2$, then from Theorem 1

$$\begin{aligned}g(t_1, t_2) &= \frac{1}{4} [(\lambda_1 + \delta t_2)(\lambda_2 + \delta t_1) - \delta] \\ &\quad \times \exp\left(-\frac{1}{2}(\lambda_1 t_1 + \lambda_2 t_2 + \delta t_1 t_2)\right) \\ &\quad \times \frac{\lambda_1 + \delta t_2}{\lambda_1 + \delta t_1} \left[\frac{\exp(-\lambda_2 t_2 - \delta t_1 t_2)}{\exp(-\lambda_2 t_1 - \delta t_1^2)} \right], \\ 0 &\leq t_1 \leq t_2\end{aligned}\quad (16)$$

and

$$\begin{aligned}g(t_1, t_2) &= \frac{1}{4} [(\lambda_1 + \delta t_2)(\lambda_2 + \delta t_1) - \delta] \\ &\quad \times \exp\left(-\frac{1}{2}(\lambda_1 t_1 + \lambda_2 t_2 + \delta t_1 t_2)\right) \\ &\quad \times \frac{\lambda_2 + \delta t_1}{\lambda_2 + \delta t_2} \left[\frac{\exp(-\lambda_1 t_1 - \delta t_1 t_2)}{\exp(-\lambda_1 t_2 - \delta t_2^2)} \right], \\ 0 &\leq t_2 \leq t_1\end{aligned}\quad (17)$$

Concluding Remarks

In this article, we describe several extensions of univariate imperfect repair models to multivariate imperfect models. These models are applicable for situations where a system has k components that are related. It should be noted that proposed models in this article do not incorporate any maintenance schedule or cost. For such models, we refer you to Li and Xu [19], Wang and Zhang [13], and many references cited there.

NADER EBRAHIMI

General Minimal Repair Models

Introduction

We consider a system subject to random deterioration and failure. At failures, repairs or replacements are performed and the system resumes operation. To model this situation we have to describe the condition of the system after the maintenance (repair/replacement) action has been performed. Some typical cases are:

- The **maintenance action** is a major repair that brings the unit to a condition that is considered to be as good as new, or equivalently, the unit is physically replaced by a new and identical unit. This maintenance action is referred to as a *replacement* [1, 2].
- The maintenance action is such that the unit is considered to be as good as it was immediately before the failure occurred. This maintenance action is referred to as a (statistical) *minimal repair*.
- The maintenance action brings the unit to a condition that is somewhere between the result of a replacement and a **minimal repair**.
- The result of the maintenance action is unsuccessful, for example in the way that the wrong part is replaced/repared or that some damage is inflicted on the unit during the maintenance. This could result in a higher failure proneness, and is often referred to as an *imperfect repair* [3].
- In some occasions information about the cause of failure makes it possible to improve the unit. The result of the maintenance action could then be an improved failure intensity of the unit.

Of course, when developing a model of a system it is important to strike a balance between the following two desired properties. The model needs to be simple enough so that it can be used to study the system by mathematical/statistical methods, and it must be a sufficiently accurate representation of the system.

In this article we restrict attention to the minimal repairs. Using the minimal repair concept it is possible to describe in a simple way the fact that many repairs in real life bring the system to a condition which is basically the same as it was just before the

failure occurred. Such a repair may be used to model a system where a component of the system is replaced or repaired. Of course, the purpose of the repair action is not to bring the system to the exact same condition. Rather the purpose is to bring the system back to operation as soon as possible. But by looking at the condition of the system after the repair, it is a reasonable assumption to say that the system state has not changed.

To formalize this idea, assume that the system is installed at time $t = 0$ and is subject to failure at a random time T_1 . The system has a failure rate (intensity) at time t given by the function $\lambda(t)$, meaning that the probability that the system fails during the interval $(t, t + h)$ is $\lambda(t)h$ if the system has survived until time t . Here h is a small number. Suppose the repair is minimal in the sense that the state or condition of the system is as good as it was immediately before the failure occurred. The minimal repair means that the age of the system is not disturbed by the failures. Consequently the failure rate at time t is $\lambda(t)$ independent of the number of failures occurred up to time t . We ignore the duration of the repairs. If N_t represents the number of failures in the time period $[0, t]$, it follows that N_t is a nonhomogeneous **Poisson process** with **intensity function** $\lambda(t)$.

This is the basic minimal repair model presented in 1960 by Barlow and Hunter [4]. This model has been extended in many ways since then, see for example Aven [5, 6], Aven and Jensen [7, 8], Phelps [9], Bergman [10], Block *et al.* [11], Stadjé and Zuckerman [12], Shaked and Shanthikumar [13], Beichelt [14], Zhang and Jardine [15], Finkelstein [16], and Zequeira and Berenguer [17]. A Bayesian approach is presented and discussed in Mazzuchi and Soyer [18].

Many special cases of the basic minimal repair model have been addressed in the literature. Two of the most frequently studied special cases are

$$\lambda(t) = \lambda\beta(\lambda t)^{\beta-1} \text{ (power law, [19])} \quad (1)$$

$$\lambda(t) = \lambda e^{\beta t} \text{ (log-linear model)} \quad (2)$$

In this article we focus on extensions of the basic model, and give special attention to the general minimal repair models presented and discussed by Aven [5] and Aven and Jensen [8].

2 General Minimal Repair Models

The minimal repair models are used to describe and predict the performance of **repairable systems**. A number of applications relate to optimal maintenance and replacement policies, see the references cited above and [1, 2]. A simple application is presented in the section titled “An Application to Optimal Replacement”.

In the literature it is often distinguished between a physical minimal repair and a statistical minimal repair (also referred to as a *black box minimal repair*) are often considered different from each other, see for example Aven and Jensen [7] and Boland and El-Newehi [20]:

- If a component of a complex system is replaced, the system as a whole is in approximately the same condition as it was immediately before the failure occurred (physical minimal repair).
- The system is repaired and the repair brings the system back into the same state it was in just prior to the failure (statistical minimal repair).

If we ignore the information about the state of the component in the physical minimal repair case, the repair is an approximate statistical minimal repair. This shows the importance of clarifying the information level. It makes a difference whether all components of a complex system are observed or only failure of the whole system is recognized. In the first case we have information about the condition of a specific component of the system, whereas in the second case the only information about the condition of the system is the age. Hence a minimal repair in the statistical case would mean replacing the system by another one of the same age that has not yet failed.

Example 1 We consider a simple two-component parallel system with independent distributed component lifetimes X_1, X_2 and allow for exactly one minimal repair. For both components the lifetime distribution is exponential with parameter 1 (denoted $\text{Exp}(1)$).

- Physical minimal repair (statistical repair at component level). After failure at $T_1 = X_1 \vee X_2$, that is at the largest lifetime, the component that caused the system to fail is repaired minimally (statistical minimal repair). Since the component lifetimes are exponentially distributed, the additional lifetime is given by an $\text{Exp}(1)$ random

variable X_3 independent of X_1 and X_2 . The total lifetime $T_1 + X_3$ has distribution

$$P(T_1 + X_3 > t) = e^{-t}(2t + e^{-t}) \quad (3)$$

- Statistical minimal repair at system level. The lifetime $T_1 = X_1 \vee X_2$ until the first failure of the system has distribution $P(T_1 \leq t) = (1 - e^{-t})^2$ and failure rate $\lambda(t) = 2 \frac{1 - \exp(-t)}{2 - \exp(-t)}$. The additional lifetime $T_2 - T_1$ until the second failure is assumed to have conditional distribution

$$\begin{aligned} P(T_2 - T_1 \leq x | T_1 = t) &= P(T_1 \leq t + x | T_1 > t) \\ &= 1 - e^{-x} \frac{2 - e^{-(t+x)}}{2 - e^{-t}} \end{aligned} \quad (4)$$

Integrating leads to the distribution of the total lifetime T_2 :

$$\begin{aligned} P(T_2 > t) &= e^{-t}(2 - e^{-t}) \\ &\quad \times (1 + t - \ln(2 - e^{-t})) \end{aligned} \quad (5)$$

It is (perhaps) no surprise that the total lifetime after a statistical minimal repair is stochastically greater than that after a physical minimal repair:

$$P(T_2 > t) \geq P(T_1 + X_3 > t), \text{ for all } t \geq 0 \quad (6)$$

We see that there is a need for being precise about the level of information. This leads us to the modern framework of point processes, which allow us to specify the failure intensity as a function of the history of the system and incorporate information about the condition of the system for example through measurements of wear characteristics and damage inflicted on the system. This framework provides a general setup for analyzing repairable systems and minimal repairs in particular. We refer to works by Aven [5, 6, 21], Aven and Jensen [7, 8], Bergman [10], Arjas and Norros [22], and Natvig [23].

A General Minimal Repair Model

Let X_t , $t \geq 0$, be an observable stochastic process, possibly a vector process, representing the condition of the system at time t . We define N_t as the number of failures in $[0, t]$. The failure intensity process, which is denoted λ_t , may depend on X_s , $0 \leq$

$s \leq t$. Often we can formulate the relation in the following way:

$$\lambda_t = v(X_t) \quad (7)$$

where $v(x)$ is a positive deterministic function. The interpretation of λ_t is that given the history of the system up to time t , the probability that the system fails in the interval $(t, t+h)$ is approximately $\lambda_t h$. In other words, λ_t is the expected number of failures per unit of time, given the information up to time t .

If the failure intensity process depends only on the state process X_t and not on the failure process N_t , we can interpret the repairs as minimal: a repair that changes neither the age of the system nor the information about the condition of the system. In this case, the running information about the condition of the system can be thought to be related to a system that is always functioning.

A way of formalizing this is to assume that given the state process X , the failure process follows a nonhomogeneous Poisson process with intensity $v(X_t)$, that is N is a doubly stochastic Poisson process (Cox process) with intensity $v(X_t)$. Hence if the whole X process is known, the intensity at time t is $v(X_t)$, independent of previous failures. This process models a system which is minimally repaired, as a repair does not change the information about the condition of the system. If we know that the state is x at time t , the failure intensity is $v(x)$, independent of the history of the failure process.

If $X_t = t$ for all t , we are back to the basic minimal repair model, where N_t is a nonhomogeneous Poisson process.

Example 2 Shock model [24]. Assume that shocks occur to the system at random times, each shock causes a random amount of damage, and these damages accumulate additively. At a shock the system fails with a given probability. A system failure can occur only at the occurrence of a shock.

Let V_t denote the number of shocks in $[0, t]$, and let Y_i denote the amount of damage caused by the i th shock. We assume that V_t is a Poisson process with rate ν , and that the Y_i 's are independent and identically distributed random variables with a distribution $H(y)$. Let X_t denote the accumulated

damage in $[0, t]$, that is,

$$X_t = \sum_{i=1}^{V_t} Y_i \quad (8)$$

Now, if the system is active before time t , and the accumulated damage equals x , and a jump of size y occurs at t , then the probability of failure at this point is $p(x+y)$, where $0 < p(x) < 1$ for all x .

This model is a special case of the general setup described above. The failure intensity process of the counting process N_t equals

$$\nu \int_0^\infty p(X_t + y) dH(y) \quad (9)$$

For a formal proof of this result, see [7, 8]. These references also include extensions of this model, by allowing the probability p to depend on the number of failures occurred. However, the repairs are then not minimal repairs.

Example 3 Monotone system. Consider a binary, monotone system ϕ of n independent components. We refer to [7, 25, 26] for the definition of such a system. Let $N_i(t)$ denote the number of failures of component i in $[0, t]$, and N_t the number of system failures in the same interval. The counting process $N_t(i)$ is assumed to have an intensity process $\lambda_t(i)$. Hence the failure process of the system N_t has an intensity λ_t given by

$$\lambda_t = \sum_{i=1}^n \lambda_t(i) X_t(i) (1 - \phi(0_i, \mathbf{X}_t)) \phi(\mathbf{X}_t) \quad (10)$$

where $\phi(\cdot, \mathbf{x}) = \phi(x_1, \dots, x_{i-1}, \cdot, x_{i+1}, \dots, x_n)$.

Observe that $X_t(i)(1 - \phi(0_i, \mathbf{X}_t))\phi(\mathbf{X}_t)$ is either 0 or 1, and equals 1 if and only if the system is functioning, component i is functioning and the system fails if component i fails.

Assume now that if the system fails, it is minimally repaired in the following sense: If a component fails and causes system failure, then this component is minimally repaired (statistical minimal repair). A component that fails without causing system failure is not repaired.

We assume that component i when not being repaired has a lifetime R_i with distribution function $F_i(t)$ and failure rate equal to $r_i(t)$. The n components are assumed to be independent.

4 General Minimal Repair Models

It follows that we have a special case of the general setup with λ_t having the form equation (10) with $\lambda_t(i) = r_i(t)X_t(i)$. The process $X_t(i)$, $t \geq 0$, is in this case either identical to 1, or 1 up to R_i and then 0. If component i is in series with the rest of the system, then $X_t(i) \equiv 1$.

Formal Mathematical Setup and Definition of a Minimal Repair

Let (T_n) , $n \in \mathbb{N}$, where $\mathbb{N} = \{1, 2, \dots\}$, be a point process on a basic probability space $(\Omega, \mathcal{F}, P)$ describing the failure times at which instantaneous repairs are carried out, that is, (T_n) is an increasing sequence of positive random variables which may also take the value $+\infty$: $0 < T_1 \leq T_2 \leq \dots$. The inequality is strict unless $T_n = \infty$. We always assume that $T_\infty = \lim_{n \rightarrow \infty} T_n = \infty$. The corresponding counting process $N = (N_t)$, $t \in \mathbb{R}_+$,

$$N_t(\omega) = \sum_{n \geq 1} I(T_n(\omega) \leq t) \quad (11)$$

where $I(\cdot)$ denotes the indicator function, represents the number of failures up to time t . Here $\mathbb{R}_+ = [0, \infty)$.

The information up to time t is represented by the pre- t -history (σ algebra) $\mathcal{F}_t$, which contains all events of $\mathcal{F}$ that can be distinguished up to and including time t . The filtration $\mathbb{F} = (\mathcal{F}_t)$, $t \in \mathbb{R}_+$, is assumed to follow the usual conditions of completeness and right continuity. The main assumption now is that the failure counting process is integrable and admits an $\mathbb{F}$ -intensity $\lambda = (\lambda_t)$, that is a decomposition

$$N_t = \int_0^t \lambda_s ds + M_t \quad (12)$$

with a mean zero martingale $M = (M_t)$. The question now is which counting processes can be classified as minimal repair processes (MRPs) and which not.

Different types of repair processes are characterized by different intensities, λ . The repairs are minimal if the intensity λ is not affected by the occurrence of failures or in other words, if one cannot determine the failure time points from the observation of λ . More formally, minimal repairs can be characterized as follows.

Definition 1. Let (T_n) , $n \in \mathbb{N}$, be a point process with an integrable counting process N and corresponding $\mathbb{F}$ intensity λ . Suppose that $\mathbb{F}^\lambda = (\mathcal{F}_t^\lambda)$, $t \in$

$\mathbb{R}_+$, is the filtration generated by λ : $\mathcal{F}_t^\lambda = \sigma(\lambda_s, 0 \leq s \leq t)$. Then the point process (T_n) is called an MRP if none of the variables T_n , $n \in \mathbb{N}$, for which $P(T_n < \infty) > 0$, is an $\mathbb{F}^\lambda$ stopping time, that is for all $n \in \mathbb{N}$ with $P(T_n < \infty) > 0$ there exists $t \in \mathbb{R}_+$ such that $\{T_n \leq t\} \notin \mathcal{F}_t^\lambda$.

This is a rather general definition which comprises a lot of special cases. It is easily verified that the nonhomogeneous Poisson process with a time-dependent deterministic function $\lambda_t = \lambda(t)$ is an MRP, because here $\mathcal{F}_t^\lambda = \{\Omega, \emptyset\}$ for all $t \in \mathbb{R}_+$, so clearly the failure times T_n are not $\mathbb{F}^\lambda$ stopping times.

If the intensity is not deterministic but a random variable $\lambda(\omega)$ which is known at the time origin (λ is $\mathcal{F}_0$ -measurable) or, more generally, $\lambda = (\lambda_t)$ is a stochastic process such that λ_t is $\mathcal{F}_0$ -measurable for all $t \in \mathbb{R}_+$, that is $\mathcal{F}_0 = \sigma(\lambda_s, s \in \mathbb{R}_+)$ and $\mathcal{F}_t = \mathcal{F}_0 \vee \sigma(N_s, 0 \leq s \leq t)$, then the process is called a doubly stochastic Poisson process or a Cox process. The failure (minimal repair) times are not $\mathbb{F}^\lambda$ -stopping times, since $\mathcal{F}_t^\lambda = \sigma(\lambda) \subset \mathcal{F}_0$ and T_n is not $\mathcal{F}_0$ -measurable.

The physical minimal repair in Example 1 can be extended to a point process with intensity $\lambda_t = I(X_1 \wedge X_2 \leq t)$. In this case $\mathbb{F}^\lambda$ is generated by the minimum of X_1 and X_2 . The first failure time of the system, T_1 , equals $X_1 \vee X_2$, which is not an $\mathbb{F}^\lambda$ stopping time so that this point process is an MRP according to the definition.

In the following we give another characterization of an MRP.

Theorem 1. Assume that $P(T_n < \infty) = 1$ for all $n \in \mathbb{N}$ and that there exist versions of conditional probabilities $F_t(n) = E[I(T_n \leq t) | \mathcal{F}_t^\lambda]$ such that for each $n \in \mathbb{N}$ $(F_t(n))$, $t \in \mathbb{R}_+$, is a ($\mathbb{F}^\lambda$ progressive) stochastic process.

1. Then the point process (T_n) is an MRP if and only if for each $n \in \mathbb{N}$ there exists some $t \in \mathbb{R}_+$ such that

$$P(0 < F_t(n) < 1) > 0 \quad (13)$$

2. If furthermore $(F_t) = (F_t(1))$ has P -a.s. continuous paths of bounded variation on finite intervals, then

$$1 - F_t = \exp\left\{-\int_0^t \lambda_s ds\right\} \quad (14)$$

See Aven and Jensen [8] for the proof.

Example 4 We return to Example 1. We now allow for repeated minimal repairs on the component level causing system failure. Let $(X_k), k \in \mathbb{N}$, be a sequence of independent identically distributed (i.i.d.) random variables following an exponential distribution with parameter 1: $X_k \sim \text{Exp}(1)$. Then we define

$$T_1 = X_1 \vee X_2, T_{n+1} = T_n + X_{n+2}, n \in \mathbb{N} \quad (15)$$

The intensity of the corresponding counting process N is then $\lambda_t = I(X_1 \wedge X_2 \leq t)$. By elementary calculations it can be seen that

$$E[I(T_1 > t) | \mathcal{F}_t^\lambda] = P(T_1 > t | X_1 \wedge X_2 \wedge t) \quad (16)$$

is continuous and nonincreasing. According to Theorem 1 it follows that (T_n) is an MRP and that the first time to failure has conditional distribution

$$\begin{aligned} 1 - F_t &= \exp \left\{ - \int_0^t I(X_1 \wedge X_2 \leq s) ds \right\} \\ &= \exp \{ -(t - X_1 \wedge X_2)^+ \} \end{aligned} \quad (17)$$

An Application to Optimal Replacement

Consider the setup of the section titled ‘‘A General Minimal Repair Model’’. Suppose now a planned replacement of the system is scheduled at time T , which may depend on the condition of the system, that is on the process X_t . The replacement time T is a *stopping time* in the sense that the event $\{T \leq s\}$ depends on the process X_t up to time s . There is no planned replacement if $T = \infty$.

The following simple cost structure is assumed: a planned replacement of the system costs $K (> 0)$ and a repair/replacement at system failure costs $c (> 0)$.

It is assumed that the systems generated by replacements are stochastically independent and identical, the same replacement policy is used for each system and the replacement and repairs take negligible time.

The problem is to determine a replacement time minimizing the long-run (expected) cost per unit time.

Let M^T and S^T denote the expected cost associated with a replacement cycle and the expected length of a replacement cycle, respectively. We restrict attention to T 's having $M^T < \infty$ and $S^T < \infty$. Then using Theorem 3.16 of [27], the long-run (expected) cost per unit time can be written as follows:

$$B^T = \frac{M^T}{S^T} = \frac{cEN_T + K}{ET} \quad (18)$$

Using equation (12) (see also [7, 28]), it follows from (18) that

$$B^T = \frac{cE \int_0^T \lambda_t dt + K}{E \int_0^T dt} \quad (19)$$

We note that the optimality criterion is in the same form as analyzed by Aven and Bergman [29]. The main results obtained in [29] are summarized below.

Introduce $a_t = c\lambda_t$ and assume that a is nondecreasing in t . Define the replacement time T_δ by the first point in time the process a_t exceeds δ , that is $a_t \geq \delta$. We assume $ET_\delta < \infty$. It can be seen that T_δ minimizes

$$M^T - \delta S^T = E \int_0^T [c\lambda_t - \delta] dt + K \quad (20)$$

The results of [29] follow. Let $B(\delta) = B^{T_\delta}$.

The stopping time T_{δ^*} , where $\delta^* = \inf_T B^T$, minimizes B^T . The value δ^* is given as the unique solution of the equation $\delta = B(\delta)$. Moreover, if $\delta > \delta^*$, then $\delta > B(\delta)$, if $\delta < \delta^*$, then $\delta < B(\delta)$; $B(\delta)$ is non-increasing for $\delta \leq \delta^*$, nondecreasing for $\delta \geq \delta^*$, and $B(\delta)$ is left-continuous.

It follows from equation (19) and Fubini's theorem that

$$B(\delta) = \frac{c \int_0^\infty E[I(a_t < \delta)\lambda_t] dt + K}{\int_0^\infty EI(a_t < \delta) dt} \quad (21)$$

Hence if

$$a_t = cv(X_t) \quad (22)$$

where $v(x)$ is a deterministic function in x , and $Q_t(\cdot)$ is the distribution of X_t , we may write

$$B(\delta) = \frac{c \int_0^\infty \int I(cv(x) < \delta)v(x)Q_t(dx) dt + K}{\int_0^\infty \int I(cv(x) < \delta)Q_t(dx) dt} \quad (23)$$

Note that if X_t is a vector process, then one of the components of X_t may be the time t .

Examples of applications can be derived from the models presented in Examples 2 and 3 above (Aven [30]). For example, for the shock model the $v(x)$ function is given by

$$v(x) = v \int_0^{\infty} p(x+y) dH(y) \quad (24)$$

Analysis of Recurrent Events from Repairable Systems

Recurrent Events

In many disciplines, the event of interest occurs on a recurring basis. For example, in the engineering, quality, and reliability setting, recurrent events include the failure of a mechanical or electrical component, the discovery of bugs in a computer software, the appearance of cracks in a concrete edifice, the occurrence of industrial accidents in a plant, or the breakdown of fibers in a fiber bundle. In the biomedical and public health setting, examples are the occurrence of epileptic seizures, hospitalization of patients with chronic diseases, and emergence of tumors. In the social and political sciences, civil disturbances (e.g., race riots, strikes by union members), international conflicts, or brushes with the law by a juvenile delinquent are recurrent events. More generally, monitoring the status of a repairable system leads to a recurrent event. Ascher and Feingold [1] defined a repairable system as a system which, after failing to perform one or more of its functions satisfactorily, can be restored to fully satisfactory performance by any method other than the replacement of the entire system. Examples of real recurrent event data sets in the literature are the air-conditioning data examined in Proschan [2], the gastroenterology data in Aalen and Husebye [3], and the data in Table 2.7 in Blischke and Murthy [4], which is depicted in Figure 1 which provides the times between successive failures of hydraulic components of load-haul-dump (LHD) machines that were used in moving ore and rock in underground mines in Sweden.

Because the recurrent event can potentially occur more than once within an experimental unit, it is important to take into account associations among the interevent times. Realistically, the distribution of an interevent time will also depend on the history up to the time of the last event occurrence. For example, knowing when a mechanical component has failed thus far, and the number of observed failures, will affect the time to the next failure of the component. Therefore, the usual assumption of independent and identically distributed (i.i.d.)

Figure 1 A pictorial depiction of the load-haul-dump (LHD) machine recurrent event data set from Table 2.7 of Blischke and Murthy [4]

interevent times will typically be untenable. Furthermore, interventions (e.g., corrective measures) will usually be performed at each event occurrence. Going back to the mechanical component, upon its breakdown, the intervention will either come in the form of repair or a replacement of this component. The type of intervention performed will therefore partially affect the distribution of the time to the next breakdown of the component. When modeling recurrent events, it becomes imperative that these aforementioned factors be taken into account to arrive at so-called dynamic models.

Software reliability provides a poignant setting for such dynamic recurrent event models. The simplest and classic model in this area is the Jelinski and Moranda (JM) [5] model which postulates that the distribution of the interfailure time of a software depends on the number of bugs remaining in the software and an unknown parameter encoding the contribution of each remaining bug to the interfailure time. The mathematical description of this model will be described later as it is a special case of a general dynamic recurrent event model. The JM model was extended in Agustin and Peña [6] where a series system of m component software's is considered, so the failure of a component software leads to the failure of the software system. In the Agustin and Peña [6] paper, the goal is to perform a debugging of the software system to develop a deployable system which can successfully complete, at a prespecified reliability or success probability, a given task whose completion time may be random. In the debugging stage of this software system during its development, there

are $m + 1$ types of recurrent events: the m failures attributable to each of the component software, and the completion of the assigned task. The JM model and the extension in [6] are examples of dynamic recurrent event models. They go beyond the simplistic i.i.d. model for interevent times.

In this article, we provide a review of dynamic models for recurrent events, and also discuss statistical inference procedures for these dynamic models. Inference procedures will be those pertaining to parameter **estimation**, as well as those that deal with goodness-of-fit (GOF) issues for the class of models. The section titled “Models for Recurrent Events” will discuss recurrent event models, while the section titled “Inference Procedures” will deal with the inferential aspects. A demonstration of the procedures will be performed using the LHD data set. Concluding remarks will be provided in the last section.

Models for Recurrent Events

In this article, we impose the simplifying assumption that repairs take negligible time and hence our focus is just on the operational time. Consider a component placed on test at (calendar) time 0. Let $0 = S_0 < S_1 < S_2 < \dots$ denote the successive times of event occurrences and let $T_i = S_i - S_{i-1}$, $i = 1, 2, \dots$, denote the interevent times. The history of the process will be denoted by $\mathbf{F} = \{\mathcal{F}_s : s \geq 0\}$, which is an increasing, right-continuous collection of σ fields. This history is also called a *filtration*, and $\mathcal{F}_s$ contains information about the component which includes the number of recurrent event occurrences up to time s , **covariate** information, and the type of intervention that were performed. Owing to the dynamic nature in which recurrent events are monitored and the need to cogently incorporate the effects of performed interventions, it is more natural and beneficial to use hazard rate functions instead of density functions in modeling. Recall that for a continuous interevent time $T \geq 0$ with density function $f(t)$ and distribution function $F(t)$, its hazard rate function and cumulative hazard function are defined, respectively, via

$$\lambda(t) = f(t)/[1 - F(t)] \quad \text{and} \quad \Lambda(t) = -\log[1 - F(t)] = \int_0^t \lambda(v) dv \quad (1)$$

The hazard rate function has the intuitive interpretation that for small positive h , $\lambda(t)h$ is approximately the probability that $t \leq T \leq t + h$, given the information that $T \geq t$. In addition to their ability to describe qualitative aspects of a failure process over time, hazard rate functions enable the use of the modern stochastic process approach to event-time analysis, which is the mathematical framework adopted in this article. This framework is anchored in the theory of counting processes, martingales, and stochastic integration as seminally introduced by Aalen [7]. Excellent presentation of this framework can be found in Andersen *et al.* [8] and Fleming and Harrington [9].

The number of occurrences of the recurrent event is represented by the stochastic process $\{N(s) : s \geq 0\}$, where $N(s) = \sum_{i=1}^{\infty} I\{S_i \leq s\}$. On the other hand, the process $\{A(s) : s \geq 0\}$ is a nondecreasing process measurable with respect to $\mathcal{F}_{s-}$ such that $\{M(s) = N(s) - A(s), s \geq 0\}$ is a square-integrable zero-mean martingale. The process $A(s)$ is called the *compensator* of N . It is usually assumed to have the form

$$A(s) = \int_0^s \lambda(w) dw = \int_0^s Y(w)\alpha(w) dw \quad (2)$$

where $\{\alpha(s) : s \geq 0\}$ is a measurable process with respect to $\mathcal{F}_{s-}$ and $\{Y(s) : s \geq 0\}$ is an at-risk process with $Y(s) = 1$ if the component is still under observation at time s and $Y(s) = 0$ otherwise. The process $\lambda(s) = Y(s)\alpha(s)$ is referred to as the *intensity rate process*. The process $\alpha(s)$ may depend on some baseline hazard rate function.

A heuristic way to view the above model is as follows. Consider an infinitesimal interval $[s, s + ds)$ and suppose we are given all the information that has accrued just before time s , formally encapsulated by the σ field $\mathcal{F}_{s-}$. Then the change in N over this interval, denoted by $dN(s) = N((s + ds)-) - N(s-)$, could be viewed as a Bernoulli random variable with success probability of $dA(s) = Y(s)\alpha(s) ds$. As such,

$$E\{dN(s)|\mathcal{F}_{s-}\} = Y(s)\alpha(s) ds \quad \text{and} \quad (3)$$

$$\begin{aligned} \text{Var}\{dN(s)|\mathcal{F}_{s-}\} &= (Y(s)\alpha(s) ds)(1 - Y(s)\alpha(s) ds) \\ &\approx Y(s)\alpha(s) ds \end{aligned} \quad (4)$$

One of the early dynamic models for **repairable systems** is the imperfect repair model of Brown and

Proschan [10]. In this model, a component that fails at time s is repaired either perfectly with probability p , or minimally with probability $1 - p$, where $p \in [0, 1]$. A perfect repair restores the component to the good-as-new state, whereas a **minimal repair** restores the component to its state just prior to failure. Hence, the time to the next failure of a minimally repaired component is stochastically equivalent to that of a working component of the same age. If we take the extreme case where $p = 1$, which is akin to replacing the failed component with a new one, then the interevent times T_i 's are i.i.d. and therefore a renewal process can be used to model the interevent times. On the other hand, if $p = 0$, then a time-transformed nonhomogeneous **Poisson process** is the model of choice. This **imperfect repair** model was further extended by Block, Borges, and Savits [11] to the so-called BBS model by letting the probability of perfect repair p to be time dependent. Hence, upon failure at time s , a component is repaired perfectly with probability $p(s)$, or minimally with probability $1 - p(s)$. For both models, the effective age of a component just after a repair will be one of two possible values: (a) zero, if the component was repaired perfectly or (b) identical to the effective age just prior to failure, if minimal repair was performed.

To accommodate modes of repair other than the two extremes of minimal and perfect, Dorado *et al.* [12] introduced a general repair model where the effective age of a component after repair can possibly be less than its effective age just prior to failure. To describe their model, for a component, define sequences $\{A_j : j = 1, 2, \dots\}$ and $\{\phi_j : j = 1, 2, \dots\}$, which are referred to as the *effective ages* and *life supplements*, respectively, and such that $A_1 = 0$, $\phi_1 = 1$, $A_j \geq 0$, $\phi_j \in (0, 1]$ with

$$A_j \leq A_{j-1} + \phi_{j-1}T_{j-1}, j = 1, 2, \dots \quad (5)$$

Defining the effective age just prior to the j th failure as $X_j = A_j + \phi_j T_j$ enables us to write equation (5) as $A_j \leq X_{j-1}$. It is clear that smaller values of ϕ_j result in smaller effective ages, hence the term life supplement. By choosing A_j and ϕ_j appropriately, other known models for repairable systems such as the Brown and Proschan model as well as the models proposed by Kijima [13] can be obtained. For instance, if we let $\phi_j = 1$ for each j and

$$A_j = \sum_{k=1}^{j-1} \left[\prod_{i=k}^{j-1} D_i \right] T_k = D_{j-1}(A_{j-1} + T_{j-1}), \quad j = 1, 2, \dots \quad (6)$$

where D_j is a random variable such that $D_j = 0$ with probability p and $D_j = 1$ with probability $1 - p$, then we get the Brown and Proschan [10] model.

Recognizing that it is not only the type of intervention that affects the distribution of successive interevent times, Peña and Hollander [14] developed a more general dynamic recurrent event model. In particular, they noted that other concomitant variables may have an effect, together with unobservable variables which may induce dependencies among the interevent times. Their model uses an intensity process that depends on the interaction of four factors, namely, the effect of the interventions undertaken, the number of event occurrences, the presence of covariates, and the impact of unobservable frailty components. Due to the interplay of these various factors, it is not necessary for a repaired component to be better than its state just prior to failure, that is, a repair may put the component in a worse state relative to the state just before the most recent failure. An example of this is imperfect debugging in software reliability where more bugs may be introduced in the process of removing a bug.

The model by Peña and Hollander postulates an intensity rate process for a component with a covariate vector $\mathbf{X} = (X_1, \dots, X_m)^t$ and a positive frailty component Z of form

$$\lambda(s|Z, \mathbf{X}) = Y(s)Z\lambda_0(\mathcal{E}(s))\rho(N(s-); \alpha)\psi(\boldsymbol{\beta}^t\mathbf{X}) \quad (7)$$

In this model, Z has distribution $H(z; \xi)$, $\lambda_0(\cdot)$ is an unknown baseline hazard function, $\rho(\cdot; \cdot)$ is a monotone function from $\mathbf{N} = \{0, 1, 2, \dots\}$ to $\mathbf{R}_+ = [0, \infty)$ with $\rho(0; \alpha) = 1$ and α is some unknown parameter, $\psi(\cdot)$ is a known nonnegative link function from $\mathbf{R}$ to $\mathbf{R}_+$, $\boldsymbol{\beta} = (\beta_1, \dots, \beta_m)^t$ is an unknown regression coefficient vector, and $\mathcal{E}(s)$ is an observable $\mathcal{F}_{s-}$ -measurable process and satisfies (a) $\mathcal{E}(0) = e_0$, where e_0 is a nonnegative real number; (b) $\mathcal{E}(s) \geq 0$; and (c) $\mathcal{E}(s)$ is monotone and differentiable for $s \in [S_{k-1}, S_k)$ with $\mathcal{E}'(s) \in (0, 1]$. The process $\mathcal{E}(s)$ is referred to as the *effective age process* and models the

impact of the type of intervention performed at each event, whereas the function $\rho(\cdot; \cdot)$ contains the effect of the accumulating event occurrences. A value of $\rho(\cdot; \cdot)$ greater than unity indicates that the accumulation of event occurrences results in accelerating future event occurrences. On the other hand, $\rho(\cdot; \cdot) < 1$ implies a deceleration of future event occurrences. In most situations, $\rho(\cdot; \alpha)$ is a monotone function.

To illustrate the generality of this model, we present some examples to show that with appropriate choices for $\mathcal{E}(\cdot)$ and $\rho(\cdot; \cdot)$ in equation (7), some of the well-known models are obtained. Note that in these examples we do not have the frailty component, that is, $Z = 1$.

Example 1 If $\mathcal{E}(s) = s - S_{N(s-)}$, the backward recurrence time, and $\rho(k; \alpha) = \alpha - k$ for some positive integer parameter α , the JM software reliability model is recovered from the Peña and Hollander model. The parameter α represents the initial number of bugs in the software at the beginning of the debugging process. An additional feature is the presence of a covariate which, in practice, could depend on a number of factors such as the ability of the individual performing the debugging of the software.

Example 2 Let $D_1, D_2, \dots$ be an i.i.d. sequence of Bernoulli random variables with success probability p . Let $v(s) = \sum_{i=1}^{N(s)} D_i$ be the number of “successes” observed up to time s and define $0 \equiv \tau_0 < \tau_1 < \tau_2 < \dots$ via $\tau_k = \min\{j > \tau_{k-1} : D_j = 1\}$, $k = 1, 2, \dots$. By setting $\rho(k; \alpha) \equiv 1$ and $\mathcal{E}(s) = s - S_{\tau_{v(s-)-}}$, the Brown and Proschan minimal repair model is obtained. Recall that a “success” is defined as a perfect repair. In addition, setting the success probability p as a function of the calendar time s results in the BBS model.

Example 3 Let $\{A_j : j = 1, 2, \dots\}$ and $\{\phi_j : j = 1, 2, \dots\}$ be two sequences satisfying equation (5). If we let $\rho(k; \alpha) \equiv 1$ and $\mathcal{E}(s) = A_{N(s-)} + \phi_{N(s-)}(s - S_{N(s-)})$ then the model reduces to the general repair model of Dorado, Hollander, and Sethuraman, with the additional feature of incorporating covariates.

For more detailed discussions of the generality of the Peña and Hollander dynamic model, refer to their paper [14] and Peña *et al.* [15].

Inference Procedures

In this section, we discuss two important inferential aspects regarding dynamic recurrent event models. We focus on model parameter estimation for the Peña and Hollander model, whereas for the GOF testing problem, we use the BBS minimal repair model. The GOF testing problem for the more general dynamic model is currently being researched.

Estimation of Parameters

The approach to estimating model parameters is *via* the maximum-likelihood principle. This entails the construction of an appropriate likelihood function, given sample data. We suppose that n independent experimental units are observed over the interval $[0, s^*]$ yielding the sample data

$$\mathbf{D}_i(s^*) = \{(N_i(v), Y_i(v), \mathcal{E}_i(v), \mathbf{X}_i(v)), v \in [0, s^*]\}, \\ i = 1, 2, \dots, n \quad (8)$$

For the i th unit there is also an unobservable frailty variable Z_i , where $Z_1, Z_2, \dots, Z_n$ are assumed to be i.i.d. from a gamma distribution $H(\cdot|\xi)$ with unit mean and variance $1/\xi$, where ξ is unknown. The case where ξ is made to approach ∞ coincides with the model without frailty. The model parameters are α, β, ξ , and $\lambda_0(\cdot)$. For brevity, we let $\delta = (\lambda_0(\cdot), \alpha, \beta)$.

Given $Z_i = z_i$, and invoking the heuristic conditionally Bernoulli interpretation of the model, with $B_i(v; \delta) = Y_i(v) \lambda_0[\mathcal{E}_i(v)] \rho[N_i(v-); \alpha] \psi(\mathbf{X}_i(v)^t \beta)$ the likelihood contribution of the i th unit is given by

$$L_{C,i}(\delta; s^*) \\ = \prod_{v=0}^{s^*} [z_i B_i(v; \delta)]^{\Delta N_i(v)} [1 - z_i B_i(v; \delta)]^{1 - \Delta N_i(v)} \\ = \left\{ \prod_{v=0}^{s^*} [z_i B_i(v; \delta)]^{\Delta N_i(v)} \right\} \exp \left\{ -z_i \int_0^{s^*} B_i(v; \delta) dv \right\} \quad (9)$$

The likelihood function, conditional on $Z_i = z_i$, $i = 1, 2, \dots, n$, becomes $L_C(\delta; s^*) = \prod_{i=1}^n L_{C,i}(\delta; s^*)$. Multiplying this conditional likelihood by $\prod_{i=1}^n h(z_i|\xi)$, where $h(z|\xi) = \xi^\xi z^{\xi-1} \exp(-\xi z) / \Gamma(\xi)$ for $z \geq 0$ is the gamma density function associated with $H(z|\xi)$, then integrating over $z_i \in [0, \infty)$, $i =$

$1, 2, \dots, n$, yields the unconditional likelihood function given by

$$L(\delta, \xi; s^*) = \prod_{i=1}^n \left\{ \left(\frac{\xi}{\xi + \int_0^{s^*} B_i(v; \delta) dv} \right)^\xi \times \prod_{v=0}^{s^*} \left[\frac{(N_i(v-) + \xi) B_i(v; \delta)}{\xi + \int_0^{s^*} B_i(v; \delta) dv} \right]^{\Delta N_i(v)} \right\} \quad (10)$$

This likelihood simplifies under the no-failty setting by letting $\xi \rightarrow \infty$ or setting $z_i = 1, i = 1, 2, \dots, n$, to

$$L(\delta; s^*) = \prod_{i=1}^n \left[\left\{ \prod_{v=0}^{s^*} [B_i(v; \delta)]^{\Delta N_i(v)} \right\} \times \exp \left\{ - \int_0^{s^*} B_i(v; \delta) dv \right\} \right] \quad (11)$$

Two cases need to be considered in the estimation procedure. The first case is when the unknown baseline hazard rate function $\lambda_0(\cdot)$ is assumed to belong to some known parametric family of hazard rate functions $\mathcal{C} = \{\lambda(t|\theta) : \theta \in \Theta\}$ with the parameter θ unknown, such as for example when $\mathcal{C}$ is the Weibull class of hazard rate functions with members $\lambda(t|\theta_1, \theta_2) = (\theta_1 t)^{\theta_2}$ for positive parameters θ_1 and θ_2 . The model parameters to be estimated are therefore $\delta = (\theta, \alpha, \beta)$ and ξ . The maximum likelihood ML estimates $(\hat{\delta}, \hat{\xi})$ of these parameters could be obtained by direct maximization of the likelihood function $L(\delta, \xi; s^*)$ in equation (10) using iterative methods, or an expectation-maximization (EM) (*cf.*, Dempster *et al.* [16]) approach could be employed as demonstrated in Stocker and Peña [17], to which we refer the reader for details. In the EM implementation, the frailty values z_i 's are considered as missing.

In the second case, the baseline hazard rate function $\lambda_0(\cdot)$ is nonparametrically specified, so it is only assumed to be some continuous hazard rate function on $\mathfrak{N}_+ = [0, \infty)$. The model parameter therefore has an infinite-dimensional component, the $\lambda_0(\cdot)$, and finite-dimensional components, which are α, β , and ξ , hence this is referred to as a *semiparametric model*. The estimation algorithm in this semiparametric setting was presented in Peña *et al.* [15]; *see also* Kvam and Peña [18], which deals with a load-sharing dynamic semiparametric model which

is a special case of the general dynamic model. Gonzalez *et al.* [19] developed an R package (Ihaka and Gentleman [20]) called `gcmrec` which implements the algorithm in [15] for estimating the baseline cumulative hazard function $\Lambda_0(t)$ and the finite-dimensional parameters (α, β, ξ) . Properties of the resulting estimators were also examined in [15], to which we refer the reader for details of the semiparametric estimation procedure. We do not go further into details concerning the estimators in this setting, except to mention that the estimator of $\Lambda_0(t)$ is a generalization of the Aalen–Breslow–Nelson estimator of the cumulative hazard function with right-censored data. The resulting estimator of the distribution function associated with $\Lambda_0(\cdot)$ is a generalization of the Kaplan–Meier [21] or the product-limit estimator of the distribution function with right-censored data. The **EM algorithm** plays a central role in the estimation of the finite-dimensional parameters in this semiparametric setting, with the estimates obtained from a partial likelihood function which generalizes the partial likelihood under the **Cox proportional hazards** model in Cox [22] and Andersen and Gill [23].

Example 4 Let us now consider the LHD machine data set in Blischke and Murthy [4], which was first presented and analyzed in Kumar and Klefsjö [24]. Data were collected throughout the 2-year development phase from six machines of varying ages labeled as old, medium, and relatively new. We treat age as a covariate and use two dummy variables X_1 and X_2 to code the age classification as follows: old machines are coded as (0, 0), medium-aged machines as (1, 0), and relatively new machines as (0, 1). We assume that the effective age process, the accumulating event function, and the link function are of the forms $\mathcal{E}(s) = s - S_{N(s)}, \rho[N(s-); \alpha] = \alpha^{N(s-)},$ and $\psi(y) = \exp(y)$, respectively. Note that the given effective age process implies that a perfect repair is performed at each failure, while the given link function corresponds to that in the Cox proportional hazards model [22]. The relevant parameters were estimated by Stocker and Peña [17] under the assumption of a two-parameter Weibull model for the baseline hazard function, while Peña *et al.* [15] considered a nonparametric specification for the baseline hazard function. The resulting estimates of the finite-dimensional parameters are presented in Table 1. In both parametric and semiparametric scenarios, $\hat{\xi}$

6 Analysis of Recurrent Events from Repairable Systems

Table 1 Parameter estimates for the LHD data set under both parametric and nonparametric specifications of the baseline hazard function

Parameter of interest	Estimates	
	$\Lambda_0(t) = (\theta_1 t)^{\theta_2}$	Nonparametric specification for $\Lambda_0(t)$
α	1.030	1.026
β_1	-0.138	-0.076
β_2	-0.079	-0.054
ξ	16 419.81	2.53×10^{28}
θ_1	0.006	NA
θ_2	0.969	NA

turned out to be very large, thereby indicating that there is no need for a frailty component in the model.

Goodness-of-Fit Testing

Another facet of inference is **hypothesis testing**. GOF testing is one form of hypothesis testing. We examine this GOF issue in the recurrent event setting, but for the more restricted BBS model incorporating covariates. The problem of interest is to ascertain, based on sample data, whether the baseline hazard rate function $\lambda_0(\cdot)$ belongs to some specified parametric family of hazard rate functions. A solution to this GOF problem for the BBS model was presented by Agustin and Peña [25, 26] and Agustin [27]. These papers are the basis of the procedure described below, which uses the smooth embedding idea of Neyman [28] but adapted to hazard rate functions. See Rayner and Best [29] for the classical smooth GOF theory and Peña [30, 31] for its hazard-based adaptation.

Consider the situation where n repairable systems are monitored with the repair or intervention scheme following the BBS model with perfect repair probability function given by $p(\cdot)$. We assume that each system is followed until the first perfect repair. For the i th system, we denote by v_i the number of failure events observed until the first perfect repair, so by letting $S_{i1} < S_{i2} < \dots$ be the successive times of failures, the length of time until the first perfect repair is S_{iv_i} . The vector of random observables for the i th system is

$$\mathbf{D}_i = \left\{ v_i, (S_{ij}, \quad j = 1, 2, \dots, v_i), \right. \\ \left. (\mathbf{X}_i(v), v \in [0, S_{iv_i}]) \right\} \quad (12)$$

We convert this to a stochastic process notation by defining for the i th system the processes

$$N_i(s) = \sum_{j=1}^{v_i} I\{S_{ij} \leq s\} \quad \text{and} \quad Y_i(s) = I\{S_{iv_i} \geq s\} \quad (13)$$

so $\mathbf{D}_i$ is equivalent to observing $\{(N_i(v), Y_i(v), \mathbf{X}_i(v)) : v \in [0, \infty)\}$. Recall that under the BBS model with covariates we have, in differential notation,

$$\mathbf{P}\{dN_i(s) = 1 | \mathcal{F}_{s-}\} = Y_i(s) \lambda_0(s) \exp\{\mathbf{X}_i(s)^t \boldsymbol{\beta}\} ds \quad (14)$$

for some unknown baseline hazard rate function $\lambda_0(\cdot)$ and an unknown regression parameter vector $\boldsymbol{\beta}$. We require that v_i be finite with probability one, and a sufficient condition for this to hold is $\int_0^\infty p(v) \lambda(v; \xi) \exp\{\mathbf{X}_i(v)^t \boldsymbol{\beta}\} dv = \infty$.

The GOF testing problem is to test the null hypothesis (H_0) that the baseline hazard rate function $\lambda_0(\cdot)$ belongs to a prespecified parametric family of hazards $\mathcal{C} = \{\lambda_0(\cdot; \xi) : \xi \in \Xi\}$, where the functional form of $\lambda_0(\cdot; \cdot)$ is known, *versus* the alternative hypothesis (H_1) that $\lambda_0(\cdot)$ does not belong to $\mathcal{C}$. The idea behind Neyman's embedding approach, adapted to the hazard function framework, is to imbed $\mathcal{C}$ in a larger class of hazard rate functions. For this embedding, Agustin and Peña [25, 26], following Peña [30, 31], used the larger class given by

$$\mathcal{A}_k = \{\lambda_k(\cdot; \boldsymbol{\theta}, \xi) = \lambda_0(\cdot; \xi) \\ \times \exp\{\boldsymbol{\theta}^t \boldsymbol{\psi}(\cdot; \xi)\} : \xi \in \Xi, \boldsymbol{\theta} \in \mathfrak{R}^k\} \quad (15)$$

for some prespecified positive integer k and functions or processes $\boldsymbol{\psi}(\cdot; \xi) = (\psi_1(\cdot; \xi), \dots, \psi_k(\cdot; \xi))^t$. The class $\mathcal{C}$ then obtains from $\mathcal{A}_k$ by setting $\boldsymbol{\theta} = (\theta_1, \dots, \theta_k)^t = \mathbf{0}$, so that the GOF problem simplifies to testing the hypotheses

$$\begin{aligned} H_0 : \boldsymbol{\theta} = \mathbf{0}, \xi \in \Xi, \boldsymbol{\beta} \in \mathfrak{N}^m \quad \text{versus} \\ H_1 : \boldsymbol{\theta} \neq \mathbf{0}, \xi \in \Xi, \boldsymbol{\beta} \in \mathfrak{N}^m \end{aligned} \quad (16)$$

Because the parameters ξ and $\boldsymbol{\beta}$ are completely unspecified, these hypotheses are composite and ξ and $\boldsymbol{\beta}$ are nuisance.

Following the same conditionally Bernoulli argument utilized in the preceding subsection, under the class $\mathcal{A}_k$, the likelihood function associated with $\mathbf{D} = (\mathbf{D}_1, \dots, \mathbf{D}_n)$ is

$$\begin{aligned} L(\boldsymbol{\theta}, \xi, \boldsymbol{\beta}) = \prod_{i=1}^n \left\{ \left[\prod_{v=0}^{\infty} [B_i(v; \boldsymbol{\theta}, \xi, \boldsymbol{\beta})]^{\Delta N_i(v)} \right] \right. \\ \left. \times \exp \left\{ - \int_0^{\infty} B_i(v; \boldsymbol{\theta}, \xi, \boldsymbol{\beta}) dv \right\} \right\} \end{aligned} \quad (17)$$

where $B_i(v; \boldsymbol{\theta}, \xi, \boldsymbol{\beta}) = Y_i(v) \lambda_0(v; \xi) \exp\{\boldsymbol{\theta}^t \boldsymbol{\psi}(\cdot; \xi) + \mathbf{X}_i(v)^t \boldsymbol{\beta}\}$. The estimated score vector appropriate for the GOF problem is obtained from the likelihood function in equation (17) to be

$$\begin{aligned} \hat{\mathbf{U}} &= \frac{\partial}{\partial \boldsymbol{\theta}} \log L(\boldsymbol{\theta}, \xi, \boldsymbol{\beta})|_{(\boldsymbol{\theta}, \xi, \boldsymbol{\beta}) = (\mathbf{0}, \hat{\xi}, \hat{\boldsymbol{\beta}})} \\ &= \sum_{i=1}^n \int_0^{\infty} \boldsymbol{\psi}(v; \hat{\xi}) \left\{ dN_i(v) - B_i(v; \mathbf{0}, \hat{\xi}, \hat{\boldsymbol{\beta}}) dv \right\} \end{aligned} \quad (18)$$

In equation (18), $\hat{\xi}$ and $\hat{\boldsymbol{\beta}}$ are the estimators of ξ and $\boldsymbol{\beta}$, respectively, under the restriction that H_0 holds. The estimator $\hat{\boldsymbol{\beta}}$ is obtained from an appropriate partial likelihood function and it is the $\boldsymbol{\beta}$ solving the estimating equation

$$\sum_{i=1}^n \int_0^{\infty} [\mathbf{X}_i(v) - \mathbf{E}(v; \boldsymbol{\beta})] dN_i(v) = \mathbf{0} \quad (19)$$

In this estimating equation, using the notation $\mathbf{a}^{\otimes m}$ to represent 1, $\mathbf{a}$, $\mathbf{a}\mathbf{a}^t$ for $m = 0, 1, 2$, respectively, for a

vector $\mathbf{a}$, we define

$$\begin{aligned} S_{(m)}(v; \boldsymbol{\beta}) &= \frac{1}{n} \sum_{i=1}^n \mathbf{X}_i(v)^{\otimes m} Y_i(v) \\ &\times \exp(\mathbf{X}_i(v)^t \boldsymbol{\beta}), \quad m = 0, 1, 2 \end{aligned} \quad (20)$$

and $\mathbf{E}(v; \boldsymbol{\beta}) = S_{(1)}(v; \boldsymbol{\beta})/S_{(0)}(v; \boldsymbol{\beta})$. On the other hand, the estimator $\hat{\xi}$ of ξ solves the estimating equation

$$\begin{aligned} \sum_{i=1}^n \int_0^{\infty} \left\{ \frac{\partial}{\partial \xi} \log \lambda_0(v; \xi) \right\} \\ \times \left\{ dN_i(v) - B_i(v; \mathbf{0}, \xi, \hat{\boldsymbol{\beta}}) dv \right\} = \mathbf{0} \end{aligned} \quad (21)$$

Note that solving these two estimating equations will typically require iterative methods.

From the estimated score vector $\hat{\mathbf{U}}$ in equation (18), the GOF test statistic, based on the fixed smoothing order k , is the quadratic form

$$\hat{Q}_k = \frac{1}{n} \hat{\mathbf{U}}^t \hat{\mathbf{\Gamma}}^{-} \hat{\mathbf{U}} \quad (22)$$

where $\hat{\mathbf{\Gamma}}$ is the estimate of the limiting **covariance** matrix of $\hat{\mathbf{U}}/\sqrt{n}$ under H_0 , and for a matrix $\mathbf{M}$, $\mathbf{M}^{-}$ represents its generalized inverse. The specific expression for $\hat{\mathbf{\Gamma}}$, which is somewhat involved, can be found in Agustin and Peña [26]. The test proceeds by rejecting H_0 if $\hat{Q}$ exceeds $\chi_{k^*, \alpha}^2$, the $100(1 - \alpha)$ th percentile of a central χ^2 distribution with k^* **degrees of freedom**, where k^* is the rank of $\hat{\mathbf{\Gamma}}$. We mention that there is also the issue of properly choosing the smoothing order k , and whether this could be chosen adaptively or in a data-dependent manner. We do not dwell on this issue here, but refer instead to the paper [26].

There is a variety of choices for the vector of smoothing functions or processes $\boldsymbol{\psi}(\cdot; \xi)$. One possibility is a polynomial form given by $\boldsymbol{\psi}(v; \xi) = (\Lambda_0(v; \xi), \Lambda_0^2(v; \xi), \dots, \Lambda_0^k(v; \xi))^t$, where $\Lambda_0(\cdot; \xi)$ is the cumulative hazard function associated with $\lambda_0(\cdot; \xi)$. For time-independent covariates we obtain closed-form expressions for the score statistic. The ℓ th component of the estimated score

statistic $\hat{\mathbf{U}}$ is

$$\hat{U}_\ell = \frac{1}{\sqrt{n}} \sum_{i=1}^n \left[\sum_{j=1}^{v_i} R_{ij}^\ell - \exp \left\{ \mathbf{X}_i^\top \hat{\boldsymbol{\beta}} \right\} (R_{i v_i})^{\ell+1} / (\ell + 1) \right],$$

$$\ell = 1, 2, \dots, k \quad (23)$$

where, for $i = 1, 2, \dots, n$ and $j = 1, \dots, v_i$, we have $R_{ij} = \Lambda_0(S_{ij}; \hat{\xi})$, the model's generalized **residuals**. Some other forms $\psi(\cdot; \xi)$ are discussed in Peña [30, 31] for single-spell data and Agustin [27] for the repairable system setting. Through an appropriate choice of the $\psi(\cdot; \xi)$ function or process, generalizations of GOF tests by Akritas [32], Barlow *et al.* [33], and Moses' test (*cf.* Hollander and Proschan [34]; Gatsonis *et al.* [35]; Horowitz and Neumann [36]) are obtainable from the above framework.

Example 5 Let us revisit the LHD data set presented in Example 4. Agustin and Peña [26] analyzed this data set assuming a generalized BBS model and using the polynomial specification for $\psi(\cdot)$ mentioned above. For demonstration purposes, all the intermediate repairs are assumed to be minimal and the final repair a perfect one, which is in contrast to the assumption in the estimation example where all repairs were assumed perfect. The age of the machines is considered a covariate but the coding is slightly different with (1, 0) being associated with the old machines, (0, 1) with medium-aged ones, and (0, 0) with relatively new ones. The GOF problem entails testing if a constant baseline hazard rate function is appropriate for the data, that is, whether the baseline hazard rate is associated with an exponential distribution function. Hence, the hypotheses of interest are $H_0: \lambda_0(\cdot) \in \mathcal{C} \equiv \{\lambda_0(\cdot; \xi) = \xi : \xi \in (0, \infty)\}$ versus $H_1: \lambda_0(\cdot) \notin \mathcal{C}$. The estimates for the regression coefficients were obtained to be $(\hat{\beta}_1, \hat{\beta}_2) = (0.0541, -0.1028)$, while that for ξ is $\hat{\xi} = 0.0077$. The resulting values of the score test statistic for different choices of k , the smoothing order, together with their corresponding p values are $\hat{Q}_1 = 7.4503$ ($p = 0.0063$), $\hat{Q}_2 = 9.9551$ ($p = 0.0069$), $\hat{Q}_3 = 9.8112$ ($p = 0.0202$), $\hat{Q}_4 = 9.9291$ ($p = 0.0416$). All of the p values are smaller than

0.05; hence these results indicate that the constant baseline hazard model is not tenable in the light of the data.

Concluding Remarks

The general dynamic model for recurrent events discussed in this article shows promise in terms of being able to capture the various factors affecting recurrent event occurrences. The modeling and analysis of recurrent events remains a rich area for further research. For instance, the asymptotic properties of the estimators under the frailty model with the nonparametric specification of the baseline hazard rate function is still under investigation. In addition, validation techniques for ascertaining the appropriateness of the model need to be developed, possibly in analogy to the approach used for the BBS model. In the GOF problem, the problem of adaptively determining the smoothing order is also important. The data-driven approaches in Ledwina [37] and Kallenberg and Ledwina [38] may provide avenues for a successful resolution of this problem. A Bayesian framework may also be considered as an alternative approach to the analysis of recurrent events. In particular, Sinha [39] proposed a Bayesian structure for a proportional intensity model that incorporates a frailty component. A more recent work by Merrick *et al.* [40] presents a model that is useful for developing optimal **maintenance policies**.

Global and Dynamic Information Measures for Reliability

Introduction

Information theory is a discipline in applied mathematics that deals with a basic challenge in communication, namely quantification of data with the goal of enabling as much data as possible to be reliably stored on a medium and/or communicated over a channel. What might statisticians learn from information theory? Basic concepts such as entropy, Kullback–Leibler discrimination information, and mutual information have certainly played important roles in statistics [1, 2].

There are three information theoretic lines of research that have evolved in connection with reliability analysis. The first line of research is developing information functions that are specifically suitable for reliability analysis. The second area of research is developing various entropy-based diagnostics and tests of distributional hypothesis that are useful for reliability model building. The third information theoretic line of research, which has wide applications in reliability, is developing measures that quantify the amount of information about the immediate future contained in the past. In [3] we have updated these developments in the context of reliability analysis. In this chapter, our focus is strictly on information functions for reliability. We outline some recent developments.

Univariate Information Measures

Consider the problem of discriminating between two probability models F and G for distribution of a random variable X . Suppose that F and G have continuous densities f and g over the support $\mathcal{S}$, and f is absolutely continuous with respect to g . The mean information per observation $x \in \mathcal{S}$ from F for discrimination between F and G is

$$K(f : g) \equiv \int_{\mathcal{S}} f(x) \log \frac{f(x)}{g(x)} dx \geq 0 \quad (1)$$

The equality in equation (1) holds if and only if $f(x) = g(x)$ almost everywhere. $K(f : g)$ has many desirable properties. See Kullback [4] for details and Ebrahimi and Soofi [3] for a list of properties. An important property of $K(f : g)$ is invariance under transformations: If $Y = \phi(X)$ is a nonsingular transformation, then $K(f_Y : g_Y) = K(f_X : g_X)$, where f_Y and g_Y are densities of distributions induced by the transformation.

Shannon's entropy of a distribution F with continuous density f [5] is

$$H(f) \equiv H[f(x)] = - \int_{\mathcal{S}} f(x) \log f(x) dx \quad (2)$$

The entropy (equation 2) is not invariant under nonsingular transformations. If $Y = \phi(X)$, is a one-to-one transformation, then

$$H(Y) = H(X) - E \left(\log \left| \frac{d}{dY} \phi^{-1}(Y) \right| \right) \quad (3)$$

If we think of X as the lifetime of a new system, then $\mathcal{S} = \{x : x \geq 0\}$, and $K(f : g)$ and $H(f)$ are global information measures that do not change with the age of the system, and hence are static. Given the current age of a system, t , a set of interest for reliability analysis is the *residual lifetime*, $\mathcal{S}_t = \{x : x > t\}$. The residual life distributions are $F(x; t) = P(X - t \leq x | X > t)$, and $G(x; t) = P(X - t \leq x | X > t)$, with densities $f(x; t) = (f(x)/\bar{F}(t))$ and $g(x; t) = (g(x)/\bar{G}(t))$, where $\bar{F}(t) = 1 - F(t)$, $\bar{G}(t) = 1 - G(t)$ are the survival functions. The discrimination information function between the two residual life distributions is [6].

$$K(f : g; t) = \int_t^{\infty} f(x; t) \log \frac{f(x; t)}{g(x; t)} dx \quad (4)$$

For simplicity, we take $\bar{F}(0) = \bar{G}(0) = 1$. It is clear that $K(f : g; 0) = K(f : g)$. By equation (4), for each t , $K(f : g; t)$ possesses all the properties of $K(f : g)$. If we consider $\mathcal{S}_t$ as an index set, then $K(f : g; t)$ provides a dynamic discrimination information ranging over $\mathcal{S}_t$.

2 Global and Dynamic Information Measures for Reliability

The entropy of residual life distribution, referred to as *residual entropy*, is

$$\begin{aligned} H(X; t) &\equiv H(f; t) \\ &= - \int_t^\infty f(x; t) \log f(x; t) dx \\ &= 1 - \frac{1}{\bar{F}(t)} \int_t^\infty f(x) \log \lambda_F(x) dx \end{aligned} \quad (5)$$

where $\lambda_F(x) = (f(x)/\bar{F}(x))$ is the hazard function, [7]. Clearly $H(f; 0) = H(f)$.

Noting that the residual life distribution of the uniform distribution is also uniform over $\{x : t < x < b\}$, the residual entropy (equation 5) measures the lack of concentration (uncertainty due to lack of predictability) of the remaining lifetime at age t .

Another set of interest that leads to dynamic information measures is the past lifetime of a system, $\mathcal{S}_{[t]} = \{x : x \leq t\}$ (see Di Crescenzo and Longobardi [8, 9]). The discrimination information function between two past lifetime distributions $F(x; [t]) = P(X \leq x | X \leq t)$ and $G(x; [t]) = P(X \leq x | X \leq t)$ is

$$K(f : g; [t]) = \int_0^t f(x; [t]) \log \frac{f(x; [t])}{g(x; [t])} dx \quad (6)$$

where $f(x; [t]) = (f(x)/F(t))$ and $g(x; [t]) = (g(x)/G(t))$ denote the conditional densities.

The entropy of the past lifetime distribution is defined similarly,

$$\begin{aligned} H(X; [t]) &\equiv H(f; [t]) \\ &= - \int_0^t f(x; [t]) \log f(x; [t]) dx \end{aligned} \quad (7)$$

It is clear that for $t^* = \inf\{x : F(x) = 1\}$, $K(f : g; [t^*]) = K(f, g)$, and $H(f; [t^*]) = H(f)$.

The information decomposition rule gives

$$\begin{aligned} K(f : g) &= K(P_f : P_g; \mathcal{S}_t, \mathcal{S}_{[t]}) \\ &\quad + \bar{F}(t)K(f : g; t) + F(t)K(f : g; [t]) \end{aligned} \quad (8)$$

$$\begin{aligned} H(f) &= H(P_f; \mathcal{S}_t, \mathcal{S}_{[t]}) \\ &\quad + \bar{F}(t)H(X; t) + F(t)H(X; [t]) \end{aligned} \quad (9)$$

where

$$\begin{aligned} K(P_f : P_g; \mathcal{S}_t, \mathcal{S}_{[t]}) &= F(t) \log \frac{F(t)}{G(t)} + \bar{F}(t) \log \frac{\bar{F}(t)}{\bar{G}(t)} \end{aligned} \quad (10)$$

is the discrimination information between two Bernoulli distributions implied by F and G on the partition of $\mathcal{S}$ into $\mathcal{S}_t$ and $\mathcal{S}_{[t]}$, and

$$H(P_f; \mathcal{S}_t, \mathcal{S}_{[t]}) = -F(t) \log F(t) - \bar{F}(t) \log \bar{F}(t) \quad (11)$$

is the entropy of the Bernoulli distribution implied by F on the partitions $\mathcal{S}_t$ and $\mathcal{S}_{[t]}$.

Multivariate Information Measures

To avoid complexity, we will confine ourselves to the bivariate case. Extensions to multivariate information measures are given in Ebrahimi *et al.* [10]. Let (X_1, X_2) be a vector of nonnegative random variables. We may think of X_j , $j = 1, 2$, as the lifetimes of components of a system. For a new system, $f(x_1, x_2)$ and $g(x_1, x_2)$ are the joint probability density functions of the lifetime distributions of the components. The joint discrimination information function $K(f : g)$ and the joint entropy $H(f)$ are given by equations (1) and (2) with $\mathcal{S} = \{(x_1, x_2) : x_j \geq 0\}$, which are global measures that do not change with the age of the system, and hence are static.

When the system is not new, at ages $t_1, t_2, t_j \geq 0$ of its components, the bivariate residual lifetime is $\mathcal{S}_{t_1, t_2} = \{(x_1, x_2) : x_j > t_j \geq 0\}$. For new systems and minimal repairs it is reasonable to assume that $t_1 = t_2 = t$. The general case of (t_1, t_2) includes the equal ages as well as the case when the components are replaced with new components.

The joint residual lifetime distributions are $F(x_1, x_2; t_1, t_2) = P_F(X_1 \leq x_1, X_2 \leq x_2 | X_1 > t_1, X_2 > t_2)$, the residual density functions are $f(x_1, x_2; t_1, t_2) = (f(x_1, x_2)/\bar{F}(t_1, t_2))$ and $g(x_1, x_2; t_1, t_2) = (g(x_1, x_2)/\bar{G}(t_1, t_2))$ for $x_1 > t_1, x_2 > t_2$, where $\bar{F}(t_1, t_2) = P_F(X_1 > t_1, X_2 > t_2)$ and $\bar{G}(t_1, t_2) = P_G(X_1 > t_1,$

$X_2 > t_2$) are the joint survival functions. Here, again for simplicity, we take $\bar{F}(0, 0) = \bar{G}(0, 0) = 1$.

If F is absolutely continuous with respect to G , the discrimination information function between two bivariate residual lifetime distributions is [10]

$$K(f : g; t_1, t_2) = \int_{t_2}^{\infty} \int_{t_1}^{\infty} f(x_1, x_2; t_1, t_2) \times \log \frac{f(x_1, x_2; t_1, t_2)}{g(x_1, x_2; t_1, t_2)} dx_1 dx_2 \quad (12)$$

It is clear that $K(f : g; 0, 0) = K(f : g)$. For each (t_1, t_2) , $K(f : g; t_1, t_2)$ possesses all the properties of the discrimination information function $K(f : g)$. If we consider $\mathcal{S}_{t_1, t_2}$ as a bivariate index set, then $K(f : g; t_1, t_2)$ provides a bivariate dynamic discrimination information ranging over $\mathcal{S}_{t_1, t_2}$.

The joint residual entropy of an absolutely continuous distribution is given by

$$H(X_1, X_2; t_1, t_2) = - \int_{t_2}^{\infty} \int_{t_1}^{\infty} f(x_1, x_2; t_1, t_2) \times \log f(x_1, x_2; t_1, t_2) dx_1 dx_2 \quad (13)$$

The *marginal residual entropy* of X_1 given $X_1 > t_1, X_2 > t_2$ is

$$H(X_1; t_1, t_2) = - \int_{t_1}^{\infty} f_1(x_1; t_1, t_2) \times \log f_1(x_1; t_1, t_2) dx_1 \quad (14)$$

where $f_1(x_1; t_1, t_2) = \int_{t_2}^{\infty} f(x_1, x_2; t_1, t_2) dx_2$, $x_1 > t_1, x_2 > t_2$ is the marginal residual density of X_1 , given $X_1 > t_1, X_2 > t_2$. The marginal residual density and entropy of X_2 given $X_1 > t_1, X_2 > t_2$ are defined similarly.

The conditional residual density of X_j given that $X_j > t_j, X_i = x_i > t_i$ is

$$f_{j|i}(x_j|x_i; t_1, t_2) = \frac{f(x_1, x_2; t_1, t_2)}{f_i(x_i; t_1, t_2)}, \quad x_1 > t_1, x_2 > t_2 \quad (15)$$

Its entropy is denoted by $H[f_{j|i}(x_j|x_i; t_1, t_2)] = H(X_j|x_i; t_1, t_2)$, $i \neq j = 1, 2$, which in general is a function of x_i . The expected uncertainty about $X_j > t_j$ when we know $X_i > t_i, i \neq j$ is given by the *conditional residual entropy*,

$$H(X_j|X_i; t_1, t_2) = \int_{t_i}^{\infty} H(X_j|x_i; t_1, t_2) f_i(x_i; t_1, t_2) dx_i \quad (16)$$

The joint residual entropy can be decomposed as

$$H(X_1, X_2; t_1, t_2) = H(X_i; t_1, t_2) + H(X_j|X_i; t_1, t_2), \quad i \neq j, j = 1, 2 \quad (17)$$

An important question in statistics is to what extent the use of a variable X_i reduces uncertainty about predicting the outcomes of another variable X_j . The worth of an outcome x_i of X_i for predicting X_j , given that $X_1 > t_1, X_2 > t_2$, is assessed by comparing $f_j(x_j; t_1, t_2)$ and $f_{j|i}(x_j|x_i; t_1, t_2)$. Two information measures that may be used for this purpose are $K[f_{j|i}(x_j|x_i) : f_j(x_j); t_1, t_2]$ and the entropy difference

$$\vartheta(X_j|x_i; t_1, t_2) = H(X_j; t_1, t_2) - H(X_j|X_i; t_1, t_2) \quad (18)$$

In general, both $K[f_{j|i}(x_j|x_i) : f_j(x_j); t_1, t_2]$ and $\vartheta(X_j|x_i; t_1, t_2)$ depend on x_i . The nonnegative discrimination function $K[f_{j|i}(x_j|x_i) : f_j(x_j); t_1, t_2]$ quantifies the discrepancy between the marginal and conditional distributions, but it does not indicate which of the two distributions is more informative for the prediction of the outcome of X_j . The entropy difference (equation 18) may be positive or negative depending on which of the two distributions is more informative. Interestingly, the mean values of the two measures are the same and this value defines the mutual information between two variables:

$$\begin{aligned} M(X_1, X_2; t_1, t_2) &= \int_{t_i}^{\infty} \vartheta(X_j|x_i; t_1, t_2) f_i(x_i; t_1, t_2) dx_i \\ &= \int_{t_i}^{\infty} K[f_{j|i}(x_j|x_i) : f_j(x_j); t_1, t_2] \\ &\quad \times f_i(x_i; t_1, t_2) dx_i \end{aligned} \quad (19)$$

4 Global and Dynamic Information Measures for Reliability

The mutual information has the following Kullback–Leibler and entropy representations:

$$\begin{aligned} M(X_1, X_2; t_1, t_2) &= K [f(x_1, x_2; t_1, t_2) : f_1(x_1; t_1, t_2) f_2(x_2; t_1, t_2)] \\ &\quad (20) \end{aligned}$$

$$= H(X_1; t_1, t_2) + H(X_2; t_1, t_2) - H(X_1, X_2; t_1, t_2) \quad (21)$$

$$= H(X_j; t_1, t_2) - H(X_j | X_i; t_1, t_2), \quad i \neq j \quad (22)$$

By equation (20), $M(X_1, X_2; t_1, t_2) \geq 0$ and the residual lifetimes are independent if and only if $M(X_1, X_2; t_1, t_2) = 0$. Thus, $M(X_1, X_2; t_1, t_2)$ measures the extent of dependence between the residual lifetimes. Also, by equation (20), $M(X_1, X_2; t_1, t_2)$ is invariant under one-to-one transformations of each component. For new systems, $M(X_1, X_2; 0, 0) = M(X_1, X_2)$, which is a global measure of dependency, widely used in various fields.

At ages (t_1, t_2) , the bivariate support is partitioned as $\mathcal{S} = \mathcal{S}_{t_1, t_2} \cup \mathcal{S}_{[t_1], [t_2]} \cup \mathcal{S}_{t_1, [t_2]} \cup \mathcal{S}_{[t_1], t_2}$, where $\mathcal{S}_{[t_1], [t_2]} = \{(x_1, x_2) : x_j \leq t_j, j = 1, 2\}$ is the past lifetime and $\mathcal{S}_{t_i, [t_j]}, i \neq j = 1, 2$ is the residual lifetime of component i and past lifetime of component j . Dynamic information measures can be derived for these partitions, which lead to the dynamic decompositions of global bivariate information measures. For example, for the mutual information we have

$$\begin{aligned} M(X_1, X_2) &= M(Z_1, Z_2; t_1, t_2) \\ &\quad + \bar{F}(t_1, t_2) M(X_1, X_2; t_1, t_2) \\ &\quad + F(t_1, t_2) M(X_1, X_2; [t_1], [t_2]) \\ &\quad + P_F(\mathcal{S}_{[t_1], t_2}) M(X_1, X_2; [t_1], t_2) \\ &\quad + P_F(\mathcal{S}_{t_1, [t_2]}) M(X_1, X_2; t_1, [t_2]) \quad (23) \end{aligned}$$

where $M(Z_1, Z_2; t_1, t_2)$ is the mutual information between the components of the bivariate random variable (Z_1, Z_2) whose distribution is multinomial implied by F on the partitions of $\mathcal{S}$; and $M(X_1, X_2; t_i, [t_j]), i \neq j$ is the mutual information function that measures the dependency between the past lifetime of individual i and the remaining lifetime of individual j .

All terms in equation (23) are nonnegative. Thus, if the two lifetimes were originally independent, $M(X_1, X_2) = 0$, and the residual lifetimes as well

as the past lifetimes are independent. However, for two originally dependent lifetimes, the dynamic measures can be larger, smaller, or equal to $M(X_1, X_2)$, reflecting the situations that dependency between the residual and/or past lifetimes of components may increase, decrease, or remain unchanged as they age.

Applications

The residual entropies are useful for assessing whether the residual distributions become more/less informative as the components age. Examples of distributions with some memoryless entropies are given below. Sufficient conditions for monotonicity of $H(X_1, X_2; t_1, t_2)$ are given in Ebrahimi *et al.* [10]. Comparison of $H(X_j; t_1, t_2)$ with the univariate residual entropy $H(X_j; t_j)$ (equation 5) provides an assessment of the effect of considering both ages *vis á vis* only one age t_j on the uncertainty about the residual lifetime of the component j . The difference $H(X_j; t_j) - H(X_j; t_1, t_2)$ can be positive, negative, or zero. That is, considering both ages may decrease or increase the uncertainty about the residual lifetime of a component or leave it unchanged. A definite answer is possible under certain conditions [10].

The residual mutual information is useful for assessing expected information about the lifetime of a component from the knowledge of age of the other component as they age. For many purposes, a single global measure of dependence might be satisfactory for failure time data. But for equally many cases it is useful to consider the dependence in more detail. The dynamic mutual information $M(X_1, X_2; t_1, t_2)$ is a local measure, among other things, that can be used to address the concepts of early/late dependence and short-term and long-term dependence between the components of a system.

Residual information measures may be found in closed form for a few well-known distributions. In general, residual information measures are mathematically unwieldy. For some distributions, residual information measures must be studied using numerical integration.

Series and Parallel Components

Let $X_1, \dots, X_n$ be independent and identically distributed lifetimes of components of a system with distribution F_X . The lifetimes of series and **parallel**

systems are $Y_1 = \min(X_1, \dots, X_n)$ and $Y_n = \max(X_1, \dots, X_n)$.

Global Information Measures. We present a few global information measures based on results of Ebrahimi *et al.* [11].

If $f_X(x) \leq f_X(m) = M < \infty$, so m is the mode of the distribution, then for $i = 1, n$,

$$\begin{aligned} 1 - \log n - \frac{1}{n} - \log M &\leq H(Y_i) \\ &\leq 1 - \log n - \frac{1}{n} + (n-1) \log M + nH(X) \end{aligned} \quad (24)$$

The lower bound is useful for **series systems** and attainable for large systems under some important models for components' lifetime distribution, e.g., exponential and Pareto. The upper bound is useful for parallel systems with a few components [11].

For the lifetime distributions of two systems with identical components, one designed in series and one in parallel, we have

$$K(f_{Y_1} : f_{Y_n}) = K(f_{Y_n} : f_{Y_1}) = (n-1)[\psi(n) - \psi(1)] \quad (25)$$

$$M(Y_1, Y_n) = \log \left(1 - \frac{1}{n} \right) + \frac{1}{n-1} \quad (26)$$

where $\psi(z) = d \log \Gamma(z) / dz$ is the digamma function. Both information measures are free from the lifetime model F_X . The discrimination information function is also symmetric and grows with the size of the systems, $K(f_{Y_1} : f_{Y_n}) \geq K(f_{Y_1} : f_{Y_{n-1}}) \geq K(f_{Y_1} : f_{Y_2}) = 1$. The mutual information decreases with the size of the systems, $M(Y_1, Y_n) \leq M(Y_1, Y_{n-1}) \leq M(Y_1, Y_2) = 1 - \log 2$. That is, as the sizes of the two types of systems grow, their lifetime distributions become farther apart, and hence less dependent.

Discrepancy between the lifetime distribution of a component (a single-component system) and an n -component system may be measured by either of the following discrimination information functions:

$$K(f_X : f_{Y_i}) = n - \log n - 1, \quad i = 1, n \quad (27)$$

$$K(f_{Y_i} : f_X) = \frac{1}{n} - \log \left(\frac{1}{n} \right) - 1, \quad i = 1, n \quad (28)$$

These measures do not depend either on the type of the system or on F_X . Both are increasing in n . However, $K(f_{Y_i} : f_X) < K(f_X : f_{Y_i})$, $i = 1, n$,

and their difference grows rapidly with n . That is, on average, observation of failure of a component of a system is more informative for discrimination between the system and the component lifetime distributions than observation of the system's failure, irrespective of its type.

Dynamic Entropy. The residual entropy of lifetime of a series system with two identical components inherits monotonicity of the joint residual entropy completely. If $H(X_1, X_2; t, t) = 2H(X; t)$ is decreasing (increasing) in t , then $H(Y_1; t)$ is decreasing (increasing) in t . However, the parallel system inherits its monotonicity of the joint residual entropy partially. If $H(X_1, X_2; t, t) = 2H(X; t)$ is decreasing in t , then $H(Y_2; t)$ is decreasing in t [10].

Memoryless Information

Proportional Hazards. The dynamic Kullback-Leibler discrimination information function $K(f; g; t)$ is free from t if and only if the hazard functions are proportional, $\bar{G}(t) = (\bar{F}(t))^\rho$ [6]. An analogous result for $K(f; g; [t])$ is given by Di Crescenzo and Longobardi [9].

Univariate Exponential. The residual entropy $H(f; t)$ is free from t if and only if $f_\lambda(x) = \lambda e^{-\lambda x}$, $x \geq 0, \lambda > 0$. That is, memoryless residual entropy characterizes the exponential distribution [7].

Two exponential distributions with parameters λ_1 and λ_2 have proportional hazard functions. Thus $K(f_{\lambda_1} : f_{\lambda_2}; t) = K(f_{\lambda_1} : f_{\lambda_2})$ is free from t . However, the past life time information measures $K(f; g; [t])$ and $H(f; [t])$ are not free from t .

Bivariate Exponential. In the bivariate case, some residual information, e.g. the mutual information, may be free from the ages without others being so. Also, the entire set of bivariate residual information measures may be free from the ages only in certain direction, e.g. $t_1 = t_2 = t$, with or without the marginals being exponential. The following result is noteworthy. The conditional residual entropies $H(X_j | X_i; t_1, t_2)$, $j = 1, 2$, are constants free from t_1, t_2 if and only if X_1 and X_2 are independently exponentially distributed [10].

Bivariate Lack of Memory. A bivariate distribution is said to have the bivariate lack of memory (BLM) property, if

$$\bar{F}(s_1 + t, s_2 + t) = \bar{F}(s_1, s_2) \bar{F}(t, t) \quad (29)$$

[12, 13]. The BLM property (equation 29) implies that $H(X_j; t, t)$, $H(X_1, X_2; t, t)$, $H(X_j|X_i; t, t)$, and $M(X_1, X_2; t, t)$ are all free from t . However, $H(X_j; t)$ may be time dependent. The BLM property is sufficient, but not necessary for memoryless information, see the bivariate Pareto example below.

Pareto and Related Distributions

Univariate Pareto. Consider the Pareto distribution with survival function $\bar{F}_\alpha(x) = (x + 1)^{-\alpha}$, $x \geq 0, \alpha > 0$. Two Pareto distributions with parameters α_1 and α_2 have proportional hazard functions, so

$$K(f_{\alpha_1} : f_{\alpha_2}; t) = K(f_{\alpha_1} : f_{\alpha_2}) = \rho - \log \rho - 1 \quad (30)$$

where $\rho = (\alpha_2/\alpha_1)$ is free from t .

The global and residual entropies of this Pareto model are

$$H(X) = 1 + \frac{1}{\alpha} - \log \alpha \quad (31)$$

$$H(X; t) = H(X) + \log(1 + t) \quad (32)$$

Bivariate Pareto. Let X_1, X_2 have the bivariate Pareto distribution with joint survival function

$$\bar{F}_\alpha(x_1, x_2) = (1 + x_1 + x_2)^{-\alpha}, \quad x_1, x_2 > 0, \alpha > 0 \quad (33)$$

The joint entropy and mutual information of equation (33) are as follows:

$$H(X_1, X_2) = -\log[\alpha(\alpha + 1)] + (\alpha + 2) \left(\frac{1}{\alpha} + \frac{1}{\alpha + 1} \right) \quad (34)$$

$$M(X_1, X_2) = \log \left(\frac{\alpha + 1}{\alpha} \right) + \frac{1}{\alpha + 1} \quad (35)$$

The residual information measures of equation (33) are as follows:

- [1.] $H(X_j; t_1, t_2) = h(\alpha) + \log(1 + t_1 + t_2)$
- [2.] $H(X_j|x_i; t_1, t_2) = h(\alpha + 1) + \log(1 + t_j + x_i)$
- [3.] $H(X_j|X_i; t_1, t_2) = h(\alpha + 1) - \alpha^{-1} - (\alpha + 1)^{-1} + \log(1 + t_1 + t_2)$
- [4.] $H(X_1, X_2; t_1, t_2) = H(X_1, X_2) + 2 \log(1 + t_1 + t_2)$
- [5.] $M(X_1, X_2; t_1, t_2) = M(X_1, X_2)$

where $h(\alpha) = H(X)$ shown in equation (31).

All the entropies are increasing in t_j . Thus, as the components age, these distributions become less informative about the remaining lifetimes. From 1 and equation (32) we have

$$H(X_j; t_i) - H(X_j; t_1, t_2) = -\log \left(1 + \frac{t_i}{1 + t_j} \right), \quad i \neq j \quad (36)$$

which is negative and decreasing in t_i .

The residual mutual information is free from t_1 and t_2 . Note that the rate of increase of the joint residual entropy in t_1 and t_2 is exactly twice the rate of increase of its marginal entropies. This is an interesting finding because the level of dependency between the residual lifetimes remains unchanged, irrespective of the current ages of the components. This example also indicates that the BLM property is not necessary for the memoryless dependency.

The fact that the Pareto distribution has closed form dynamic information measures is particularly useful because the moment-based measures such as variance and **correlation** coefficient do not exist for the entire family.

Related Distributions. Numerous distributions can be obtained by component-wise one-to-one transformations of random variables X_j , $j = 1, 2$ that have Pareto distribution (see Asadi *et al.* [14]). Therefore, their information functions can be derived and studied *via* the information functions of F_α . The Kullback–Leibler information functions between two members of a family, obtained from F_{α_j} , $j = 1, 2$, are the same as equation (30), where α_j , $j = 1, 2$ are determined by the parameters of the transformed models. For example, Pareto and exponential are related by transformation $\phi(x) = \log(1 + x)$, thus $K(f_{\lambda_1} : f_{\lambda_2}) = K(f_{\alpha_1} : f_{\alpha_2})$. Shannon entropy of these distributions are related to $H(f_\alpha)$ by equation (3), where the expectation is taken with respect to f_α .

The mutual information functions of their bivariate versions are all given by equation (35).

Other Recent Developments

Consideration of age has led to some important insights about lifetime models. Applications to a few important models were shown here. Applications to several other important lifetime models, some tests of distributional hypotheses based on dynamic information measures, and some sample and Bayesian dynamic statistics have also been developed (see Ebrahimi *et al.* [10] and references therein).

A major application of dynamic information functions is derivation of lifetime models based on partial information about the hazard rate and mean residual functions. Asadi *et al.* [15] and [16] proposed maximum dynamic entropy (MDE) and minimum dynamic discrimination information (MDDI) procedures, respectively, for developing lifetime models. The MDE and MDDI procedures extend the maximum entropy and minimum discrimination information principles of inference to the cases when the information is given in terms of hazard rate growth inequality, residual moment inequality, or residual moment growth inequality. The results have led to MDE and MDDI characterizations of many well-known lifetime models and development of some new models. Dynamic information measures based on generalizations of Shannon entropy and Kullback–Leibler function have been also developed by Asadi *et al.* [17], Abraham and Sankaran [18], and Nanda and Paul [19].

Cumulative Damage Models Based on Gamma Processes

Introduction

General systems of components typically sustain damage or **degradation** due to usage, shocks to the system, or unusual stresses applied to the system during operation. As an example, modern high-performance materials, such as fibrous composite materials, can be viewed as complex systems in which material strength is a function of the components of the material. The components of such complex systems may not be independent, and accurate modeling of system failure is more difficult than for simpler cases with independent components. In this article, modeling cumulative damage in general systems using stochastic processes is briefly discussed.

In recent papers [1–10], the degradation or accumulating damage to a system has been assumed to behave as a well-known stochastic process, such as a Gaussian process with positive drift, a geometric **Brownian motion** process, or a gamma process. Failure of the system occurs when the cumulative damage to, or degradation of, the system reaches a certain critical level. For example, a crack that begins as a small flaw in a piece of material may grow due to cyclic loads or tensile stresses applied to the material until the crack size reaches a critical value at which the material breaks. The drawback to using a Gaussian process with positive drift representing cumulative damage to a system under study is that the process is not strictly increasing, presenting a problem in interpreting the “negative” damage that such a process models. A more realistic cumulative damage/**degradation model** is the gamma process which will be discussed here in the section titled “The Gamma Process Model”. An accelerating variable is also incorporated into the model; see also [4–7, 11–14] and other references therein. **Estimation** for the model is given in the section titled “Parameter Estimation”, and an application to fatigue failure is discussed in the section titled “Example”. A discrete cumulative damage approach is mentioned in the section titled “Concluding Remarks”.

The Gamma Process Model

In this section, we derive the theoretical statistical distribution of a system lifetime based on the gamma process and provide a simpler approximate distribution for easier computation. We also briefly describe the method of incorporating an accelerating variable into the model.

Suppose that a system or material undergoes continuous cycles of stress loads until it fails or breaks down. Then accumulating damage is increasing as cyclic loads are in progress. This is the typical case for which the cumulative damage process should be always positive and strictly increasing. One such stochastic model is the gamma process, which we use to describe this cumulative damage. Let X_t represent the amount of damage accumulation for a material at cyclic load t . It is assumed that X_t is a gamma process, with the following properties:

1. $X_t - X_s$ has a gamma distribution with shape parameter $\alpha(t - s)$ and scale β ;
2. the increments $X_v - X_u$ and $X_t - X_s$ are independent with $v > u > t > s$.

For convenience, let $Y = X_t - X_s$. Then the random variable Y has the following **probability density function**:

$$g_Y(y) = \frac{1}{\Gamma(\alpha(t-s))\beta^{\alpha(t-s)}} y^{\alpha(t-s)-1} \times \exp\left(-\frac{y}{\beta}\right), \quad y > 0 \quad (1)$$

Let S be the breakdown strength of the system with the critical level C . Then S becomes the *first-passage* time or load for the gamma process to reach the critical value C . That is, system failure occurs at S cycles of loads when X_S reaches a critical value C . With starting value $X_0 = 0$, the increment $X_t - X_0$ is distributed as the gamma with shape parameter αt and scale β . Since X_t is strictly increasing in t , we have

$$\begin{aligned} P[S > t] &= P[X_t < C] \\ &= \int_0^C \frac{1}{\Gamma(\alpha t)\beta^{\alpha t}} x^{\alpha t-1} \exp\left(-\frac{x}{\beta}\right) dx \\ &= \frac{1}{\Gamma(\alpha t)} \int_0^C \xi^{\alpha t-1} e^{-\xi} d\xi \end{aligned} \quad (2)$$

2 Cumulative Damage Models Based on Gamma Processes

Thus, the cumulative distribution function (cdf) of S is given by

$$G_S(s; C) = \frac{\Gamma(\alpha s, C)}{\Gamma(\alpha s)} \quad (3)$$

where $\Gamma(a, z)$ is the incomplete gamma function defined by $\Gamma(a, z) = \int_z^\infty \xi^{a-1} e^{-\xi} d\xi$. Differentiating the above cdf, we have the probability density function (pdf) of S given by

$$g_S(s; C) = \alpha \left\{ \Psi(\alpha s) - \log C \right\} \left\{ 1 - \frac{\Gamma(\alpha s, C)}{\Gamma(\alpha s)} \right\} + \frac{\alpha}{\Gamma(\alpha s)} \frac{C^{\alpha s}}{(\alpha s)^2} \cdot \left\{ 1 + \sum_{k=1}^{\infty} \left(\frac{\alpha s}{\alpha s + k} \right)^2 \frac{(-C)^k}{k!} \right\} \quad (4)$$

For more details about the derivation of the above pdf, refer to Park and Padgett [4].

Although the pdf in equation (4) is the exact pdf of the first load at which damage accumulation passes to the critical value, this pdf is so complex that it is very difficult to use as a model in practice. A simpler approximate distribution will be used for computation instead of equation (4). This approximate distribution can be obtained by considering the discrete version of the damage accumulation. Let N denote the discrete version of the first-passage load at which damage accumulation reaches the critical level. Assume that $Y_i = X_i - X_{i-1}$ are independent and identically distributed (i.i.d.). Then Y_i 's have gamma distributions with shape α and scale β . Since the process X_n is strictly increasing, the probability that the number of cycles to first passage of damage accumulation to the critical value exceeds n is given by

$$P[N > n] = P[X_n < C] \quad (5)$$

Using $X_n = Y_n + Y_{n+1} + \dots + Y_1$, we have

$$P[N > n] = P\left[\sum_{i=1}^n Y_i < C \right] \quad (6)$$

Since $Y_i = X_i - X_{i-1}$ are iid, it follows from the central limit theorem that

$$\begin{aligned} P[N \leq n] &\cong 1 - \Phi\left(\frac{C - \alpha\beta n}{\beta\sqrt{\alpha n}}\right) \\ &= \Phi\left(\sqrt{\alpha n} - \frac{C}{\beta\sqrt{\alpha n}}\right) \end{aligned} \quad (7)$$

where $\Phi(z)$ is the cdf of the standard **normal distribution** with the pdf given by $\phi(z) = 1/\sqrt{2\pi} \cdot e^{-z^2/2}$. After reparameterizing from β to $\xi = C/\beta$, a continuous version of N , denoted by S , can be represented by

$$G_S(s) = \Phi\left(\sqrt{\alpha s} - \frac{\xi}{\sqrt{\alpha s}}\right) \quad (8)$$

To incorporate an accelerating variable, we assume that the shape coefficient α of the gamma process is dependent on an accelerating variable L and thus we denote it as α_L . There are several acceleration (link) functions between the shape coefficient and accelerating variable that can be used. These functions yield a large family of inverse-Gaussian-type models (as in [15]) with a **covariate** or accelerating variable that can be incorporated with failure data. Some popular acceleration functions are: (a) power law ($\alpha_L = \theta_0 L^{\theta_1}$), (b) Arrhenius law ($\alpha_L = \theta_0 e^{\theta_1/L}$), (c) inverse-log law ($\alpha_L = \theta_0 (\log L)^{\theta_1}$), and (d) exponential law ($\alpha_L = \theta_0 e^{\theta_1 L}$). For more details about such accelerated test models with these link functions, refer to [12, 16–17]. See also Park and Padgett [6, 14] who extend these link functions to incorporate several accelerating variables.

Parameter Estimation

Maximum likelihood estimates (MLEs) of the parameters of the proposed model can be obtained as follows. Suppose that subjects are tested at k different values of an accelerating variable $L_1, L_2, \dots, L_k$. At each value L_i , tests are performed for n_i specimens, resulting in observed failure times or observed breaking strengths s_{ij} , $j = 1, 2, \dots, n_i$ for $i = 1, 2, \dots, k$. For estimation of an accelerated test model over all of the k acceleration levels, $L_1, L_2, \dots, L_k$, the MLEs of the unknown parameters in a given model can be obtained by maximizing the log-likelihood function

$$\ell(\alpha_L(\theta_0, \theta_1), \xi) = \sum_{i=1}^k \sum_{j=1}^{n_i} \log g_S(s_{ij}) \quad (9)$$

where $g_S(\cdot)$ is the pdf of equation (8). The maximizing values of θ_0, θ_1, ξ are denoted by $\hat{\theta}_0, \hat{\theta}_1, \hat{\xi}$, and typically must be found numerically, as in the next section.

Example

The data in this example consist of the fatigue lifetimes (in 10^5 cycles) on coupons (rectangular strips) cut from aluminum sheeting that were tested under three levels of maximum stress. The original data set is provided by Birnbaum and Saunders [18]. Three sets of data were obtained, each under a periodic loading scheme with maximum stresses (acceleration levels) of $L_1 = 2.1$, $L_2 = 2.6$, and $L_3 = 3.1$ (in 10^4 psi).

A box-and-whisker plot of the data is presented in Figure 1. A glance at the figure shows a tendency that failure lifetimes decrease as maximum stress L increases. So the accelerated testing model seems appropriate.

To compare the fit of the proposed model with a competing model, the following *overall* mean square errors (MSEs) from the fitted model to the empirical distribution, over all values of L_i for $i = 1, 2, \dots, k$, were used. Letting $\hat{G}_{n_i}(s_{ij})$ denote the empirical cdf at L_i and $G_S(s_{ij}; \hat{\theta})$ denote the fitted cdf using the MLE $\hat{\theta}$ of the parameter vector $\theta = (\theta_0, \theta_1, \xi)$, the MSEs for the fitted model can be calculated as either

$$\text{MSE}_1(G_S(\cdot; \hat{\theta})) = \frac{1}{k} \sum_{i=1}^k \frac{1}{n_i} \sum_{j=1}^{n_i} \{G_S(s_{ij}; \hat{\theta}) - \hat{G}_{n_i}(s_{ij})\}^2 \quad (10)$$

Figure 1 Box-and-whisker plot

or

$$\text{MSE}_2(G_S(\cdot; \hat{\theta})) = \frac{1}{N} \sum_{i=1}^k \sum_{j=1}^{n_i} \{G_S(s_{ij}; \hat{\theta}) - \hat{G}_{n_i}(s_{ij})\}^2 \quad (11)$$

where $N = \sum_{i=1}^k n_i$. Here, the empirical cdf $\hat{G}_{n_i}(s_{ij})$ is obtained by using so-called median rank method.

Numerically maximizing the log-likelihood function (9) when the pdf of S is given by the power-law Weibull model [13, 19] with its cdf

$$F_L(s) = 1 - \exp \left[-L^\theta \left(\frac{s}{\beta} \right)^\alpha \right] \quad (12)$$

the MLEs of the parameters are given by $\hat{\alpha} = 5.285829$, $\hat{\beta} = 162.3285$, and $\hat{\theta} = 32.93402$. For the proposed model with the power-law acceleration link, the MLEs of the parameters are $\hat{\xi} = 19.6607248$, $\hat{\theta}_0 = 0.1771115$, and $\hat{\theta}_1 = 5.9387513$. Using these MLEs, the MSEs are given by $\text{MSE}_1 = 4.823167 \times 10^{-3}$ and $\text{MSE}_2 = 4.818797 \times 10^{-3}$ for the power-law Weibull model, $\text{MSE}_1 = 4.735168 \times 10^{-3}$ and $\text{MSE}_2 = 4.733639 \times 10^{-3}$ for the proposed model. These results show that our model outperforms the power-law Weibull model.

To show these results graphically, we use Weibull plots. For such a plot, if the data are from a Weibull distribution, the estimated distribution is close to the plotted data points which form approximately a straight line. Departures from a straight line indicate departures from a Weibull distribution. Figure 2 gives the Weibull plots of the empirical cdf's (point marks) with the overall fits of the power-law Weibull model (dashed line) and the proposed model based on the gamma process (solid curve). It is easily seen from the figure that the data (empirical cdf) at each maximum stress L_i show a departure from a straight line. This suggests that a non-Weibull distribution is preferable, substantiating the use of our proposed model which more closely fits the data.

Concluding Remarks

A realistic approach to modeling cumulative damage is given here by using a gamma process incorporating an accelerating variable. The discrete version of the damage accumulation process which yielded the simpler failure distribution (8) can be used in a very

Figure 2 Weibull plot

general cumulative damage framework [5, 7]. This extends Durham and Padgett [11] which was based on Cramér's proportional growth model [20], and is briefly outlined here.

Assume that as the tensile load or stress level on a material specimen or a system is increased, the cumulative damage X_{n+1} after $n + 1$ increments of stress can be described by

$$X_{n+1} = X_n + h(X_n)\Delta_n \quad (13)$$

where Δ_n denotes the damage incurred at the $(n + 1)$ st increment and $h(\cdot)$ is the damage model function. Recently, Park and Padgett [5, 7] developed a more general cumulative damage model,

$$c(X_{n+1}) = c(X_n) + h(X_n)\Delta_n \quad (14)$$

where $c(\cdot)$ is the damage accumulation function. Based on this general framework, Park and Padgett [5, 7] improved and extended existing models. The selection of various forms of the functions $c(\cdot)$ and $h(\cdot)$ along with an appropriate stochastic process Δ_n generated several new models for material strength incorporating the size L as shown in Park and Padgett [5, 7]. The method of obtaining the MLE with an accelerating variable was also addressed in [5, 7]. It is also noteworthy that another approach to generate cumulative damage models (see [7]) can be based on Cauchy's basic functional equation.

In addition, the above discrete damage approach can be taken as the basic framework to develop a *degradation* model. A continuous version of the damage model (14) can be represented by

$$dc(X_u) = h(X_u) dD_u \quad (15)$$

This results in the cumulative damage (or level of degradation) of the system at the stress level (or time) t , given by

$$\int_0^t \frac{1}{h(X_u)} dc(X_u) = \int_0^t dD_u = D_t - D_0 \quad (16)$$

Finally, the aforementioned damage/degradation models have been further generalized by using a hypercuboidal volume approach, which can handle several accelerating variables; refer to Park and Padgett [6, 14].

Multistate Reliability Theory

Introduction

An inherent weakness of traditional reliability theory (see **Coherent Systems**) is that the system and the components are always described either as functioning or failed. Early attempts to replace this by a theory of multistate systems for multistate components were made in the late 1970s in [1, 2] and [3]. This was followed up by independent work in [4, 5] and [6] giving proper definitions of a multistate monotone system (MMS) and of multistate **coherent systems** (MCSs) and also of minimal **path and cut** vectors. Furthermore, in [7] upper and lower bounds for the availabilities and unavailabilities, to any level, in a fixed time interval, were obtained for MMSs based on corresponding information on the multistate components. These were assumed to be maintained and interdependent. Such bounds are of great interest when trying to predict the performance process of the system, noting that the exact expressions are obtainable just for trivial systems. Hence, by the mid-1980s the basic multistate reliability theory was established. A review of the early development in this area is given in [8]. Very recently probabilistic modeling of partial monitoring of components with applications to preventive system maintenance has been extended in [9] to MMSs of multistate components.

The theory was applied in [10] to an offshore electrical power generation system for two nearby oilrigs, where the amount of power that may possibly be supplied to the two oilrigs, is considered as system states. This application is also used to illustrate the theory in [9]. In [11] the theory was applied to the Norwegian offshore gas pipeline network in the North Sea, as of the end of the 1980s, transporting gas to Emden in Germany. The system state depends not only on the amount of gas actually delivered, but also to some extent on the amount of gas compressed, mainly by the compressor component closest to Emden. Recently, the first book [12] on multistate system reliability analysis and optimization was printed. The book also contains several examples of application of reliability assessment and optimization methods to real engineering problems.

Basic Concepts and Basic Bounds

Let $S = \{0, 1, \dots, M\}$ be the set of states of the system; then the $M + 1$ states represent successive levels of performance ranging from the perfect functioning level M down to the complete failure level 0. Furthermore, let $C = \{1, \dots, n\}$ be the set of components and S_i ($i = 1, \dots, n$) the set of states of the i th component. We claim $\{0, M\} \subseteq S_i \subseteq S$. Hence, the states 0 and M are chosen to represent the endpoints of a performance scale that might be used for both the system and its components. Let x_i ($i = 1, \dots, n$) denote the state or performance level of the i th component and $\mathbf{x} = (x_1, \dots, x_n)$. It is assumed that the state, ϕ , of the system is given by the structure function $\phi = \phi(\mathbf{x})$. For the following type of multistate systems a series of results can be derived.

Definition 1 A system is an *MMS* iff its structure ϕ satisfies:

- (i) $\phi(\mathbf{x})$ is nondecreasing in each argument
- (ii) $\phi(\mathbf{0}) = 0$ and $\phi(\mathbf{M}) = M$ ($\mathbf{0} = (0, \dots, 0)$, $\mathbf{M} = (M, \dots, M)$).

The first assumption says that improving one of the components cannot harm the system, whereas the second says that if all components are in the complete failure (perfect functioning) state, then the system is in the complete failure (perfect functioning) state.

We now impose some further restrictions on the structure function ϕ . The following notation is required:

$$\begin{aligned} (\cdot_i, \mathbf{x}) &= (x_1, \dots, x_{i-1}, \cdot, x_{i+1}, \dots, x_n), \\ S_{i,j}^0 &= S_i \cap \{0, \dots, j-1\} \text{ and} \\ S_{i,j}^1 &= S_i \cap \{j, \dots, M\} \end{aligned} \quad (1)$$

Definition 2 Consider an MMS with structure function ϕ satisfying

- (i) $\min_{1 \leq i \leq n} x_i \leq \phi(\mathbf{x}) \leq \max_{1 \leq i \leq n} x_i$.

If in addition $\forall i \in \{1, \dots, n\}$, $\forall j \in \{1, \dots, M\}$, $\exists (\cdot_i, \mathbf{x})$ such that

- (ii) $\phi(k_i, \mathbf{x}) \geq j$, $\phi(\ell_i, \mathbf{x}) < j$, $\forall k \in S_{i,j}^1$, $\forall \ell \in S_{i,j}^0$, we have a *multistate strongly coherent system (MSCS)*,

2 Multistate Reliability Theory

- (iii) $\phi(k_i, \mathbf{x}) > \phi(\ell_i, \mathbf{x}) \quad \forall k \in S_{i,j}^1, \quad \forall \ell \in S_{i,j}^0$, we have an MCS,
- (iv) $\phi(M_i, \mathbf{x}) > \phi(0_i, \mathbf{x})$, we have a *multistate weakly coherent system (MWCS)*.

When $M = 1$, all this reduces to the established binary coherent system (BCS) (see **Coherent Systems**). The structure function $\min_{1 \leq i \leq n} x_i$ ($\max_{1 \leq i \leq n} x_i$) is often denoted as the multistate series (parallel) structure.

Now choose $j \in \{1, \dots, M\}$ and let the states $S_{i,j}^0, (S_{i,j}^1)$ correspond to the failure (functioning) state for the i th component, if a binary approach is used. Condition (ii) above, means that for all components i and any level j , there shall exist a combination of the states of the other components, $(\cdot_i, \mathbf{x})$, such that if the i th component is in the binary failure (functioning) state, the system itself is in the corresponding binary failure (functioning) state. In general, modifying [6], condition (ii) says that every level of each component is relevant to the same level of the system, condition (iii) says that every level of each component is relevant to the system, whereas condition (iv) simply says that every component is relevant to the system.

For a BCS one can prove the following, practically very useful principle: **redundancy** at the component level is superior to redundancy at the system level except for a parallel system where it makes no difference. Assuming $S_i = S$ ($i = 1, \dots, n$) then this is also true for an MCS, but not for an MWCS.

We now discuss a special type of an MSCS. Define the indicators ($j = 1, \dots, M$) $I_j(x_i) = 1(0)$ if $x_i \geq j$ ($x_i < j$) and the indicator vector $(\mathbf{I}_j(\mathbf{x})) = (I_j(x_1), \dots, I_j(x_n))$.

Definition 3 An MSCS is said to be a *binary type multistate strongly coherent system (BTMSCS)* iff there exist binary coherent structures ϕ_j , $j = 1, \dots, M$, such that its structure function ϕ satisfies $\phi(\mathbf{x}) \geq j \Leftrightarrow \phi_j(\mathbf{I}_j, \mathbf{x}) = 1$ for all $j \in \{1, \dots, M\}$ and all $\mathbf{x}$.

Choose again $j \in \{1, \dots, M\}$ and let the states $S_{i,j}^0, (S_{i,j}^1)$ correspond to the failure (functioning) state for the i th component, if a binary approach is applied. By the definition above, ϕ_j will, from the binary states of the components, uniquely determine the corresponding binary state of the system.

In what follows $\mathbf{y} < \mathbf{x}$ means $y_i \leq x_i$ for $i = 1, \dots, n$, and $y_i < x_i$ for some i .

Definition 4 Let ϕ be the structure function of an MMS and let $j \in \{1, \dots, M\}$. A vector $\mathbf{x}$ is said to be a *minimal path (cut) vector to level j* iff $\phi(\mathbf{x}) \geq j$ and $\phi(\mathbf{y}) < j$ for all $\mathbf{y} < \mathbf{x}$ ($\phi(\mathbf{x}) < j$ and $\phi(\mathbf{y}) \geq j$ for all $\mathbf{y} > \mathbf{x}$).

Definition 5 The *performance process of the i th component* ($i = 1, \dots, n$) is a stochastic process $\{X_i(t), t \in [0, \infty)\}$, where for each fixed $t \in [0, \infty)$ $X_i(t)$ is a random variable which takes values in S_i . The *joint performance process for the components* $\{X(t), t \in [0, \infty)\} = \{(X_1(t), \dots, X_n(t)), t \in [0, \infty)\}$ is the corresponding vector stochastic process. The *performance process of an MMS* with structure function ϕ is a stochastic process $\{\phi(\mathbf{X}(t)), t \in [0, \infty)\}$, where for each fixed $t \in [0, \infty)$, $\phi(\mathbf{X}(t))$ is a random variable which takes values in S .

Definition 6 The performance processes $\{X_i(t), t \in [0, \infty)\}$, $i = 1, \dots, n$ are *independent* in the time interval I iff, for any integer m and $\{t_1, \dots, t_m\} \subset I$ the random vectors $\{X_1(t_1), \dots, X_1(t_m)\}, \dots, \{X_n(t_1), \dots, X_n(t_m)\}$ are independent.

Definition 7 Let $j \in \{1, \dots, M\}$. The *availability*, $h_\phi^{j(I)}$ and the *unavailability*, $g_\phi^{j(I)}$ to level j in the time interval I for an MMS with structure function ϕ are given by

$$\begin{aligned} h_\phi^{j(I)} &= P[\phi(\mathbf{X}(s)) \geq j \quad \forall s \in I], \\ g_\phi^{j(I)} &= P[\phi(\mathbf{X}(s)) < j \quad \forall s \in I] \end{aligned} \quad (2)$$

Note that $h_\phi^{j(I)} + g_\phi^{j(I)} \leq 1$, with equality for the case $I = [t, t]$.

As an example of the bounds for $h_\phi^{j(I)}$ and $g_\phi^{j(I)}$ given in [7], we give the following theorem by first introducing the $n \times M$ matrices

$$\begin{aligned} \mathbf{P}_\phi^{(I)} &= \{p_i^{j(I)}\}_{j=1, \dots, M}^{i=1, \dots, n}, \\ \mathbf{Q}_\phi^{(I)} &= \{q_i^{j(I)}\}_{j=1, \dots, M}^{i=1, \dots, n} \end{aligned} \quad (3)$$

Note that according to [13] we do not need to assume that each of the performance processes of the components is associated in I .

Theorem 1 Let (C, ϕ) be an MMS with the marginal performance processes of its components being independent in I . Furthermore, for $j \in \{1, \dots, M\}$ let $\mathbf{y}_k^j = (y_{1k}^j, \dots, y_{nk}^j)$, $k = 1, \dots, n^j$ ($\mathbf{z}_k^j = (z_{1k}^j,$

$\dots, z_{nk}^j), k = 1, \dots, m^j)$ be its minimal path (cut) vectors to level j . Define

$$\ell_\phi^{j'}(\mathbf{P}_\phi^{(I)}) = \max_{1 \leq k \leq n^j} \prod_{i=1}^n p_i^{y_{ik}^{j'}(I)}$$

$$\bar{\ell}_\phi^{j'}(\mathbf{Q}_\phi^{(I)}) = \max_{1 \leq k \leq m^j} \prod_{i=1}^n q_i^{z_{ik}^{j'}+1(I)} \quad (4)$$

$$\ell_\phi^{j*}(\mathbf{P}_\phi^{(I)}) = \prod_{k=1}^{m^j} \prod_{i=1}^n p_i^{z_{ik}^{j*}+1(I)}$$

$$\bar{\ell}_\phi^{j*}(\mathbf{Q}_\phi^{(I)}) = \prod_{k=1}^{n^j} \prod_{i=1}^n q_i^{y_{ik}^{j*}(I)} \quad (5)$$

$$B_\phi^j(\mathbf{P}_\phi^{(I)}) = \max_{j \leq k \leq M} \times \left\{ \max \left[\ell_\phi^{k'}(\mathbf{P}_\phi^{(I)}), \ell_\phi^{k*}(\mathbf{P}_\phi^{(I)}) \right] \right\} \quad (6)$$

$$\bar{B}_\phi^j(\mathbf{Q}_\phi^{(I)}) = \max_{1 \leq k \leq j} \times \left\{ \max \left[\bar{\ell}_\phi^{k'}(\mathbf{Q}_\phi^{(I)}), \bar{\ell}_\phi^{k*}(\mathbf{Q}_\phi^{(I)}) \right] \right\} \quad (7)$$

Then

$$B_\phi^j(\mathbf{P}_\phi^{(I)}) \leq h_\phi^{j(I)} \leq \inf_{t \in I} \left[1 - \bar{B}_\phi^j(\mathbf{Q}_\phi^{(I,t)}) \right]$$

$$\leq 1 - \bar{B}_\phi^j(\mathbf{Q}_\phi^{(I)}) \quad (8)$$

$$\bar{B}_\phi^j(\mathbf{Q}_\phi^{(I)}) \leq g_\phi^{j(I)} \leq \inf_{t \in I} \left[1 - B_\phi^j(\mathbf{P}_\phi^{(I,t)}) \right]$$

$$\leq 1 - B_\phi^j(\mathbf{P}_\phi^{(I)}) \quad (9)$$

Here $\prod_{i=1}^n a_i \stackrel{\text{def}}{=} 1 - \prod_{i=1}^n (1 - a_i)$. By specializing $M = 1$ and $I = [t, t]$ the bounds reduce to the familiar ones from binary theory as given in [14].

An Offshore Electrical Power Generation System

The purpose of the offshore electrical power generation system considered in [9] and [10], depicted in Figure 1, is to supply two nearby oilrigs with electrical power. Both oilrigs have their own main generation, represented by equivalent generators A_1 and A_3 , each having a capacity of 50 MW. In addition oilrig 1 has a standby generator A_2 that is switched

into the network in case of outage of A_1 or A_3 . A_2 also has a capacity of 50 MW. The control unit, U , continuously supervises the supply from each of the generators with an automatic control of the switches. If, for instance, the supply from A_3 to oilrig 2 is not sufficient, whereas the supply from A_1 to oilrig 1 is sufficient, U can activate A_2 to supply oilrig 2 with electrical power through the standby subsea cables L .

The components to be considered here are A_1, A_2, A_3, U and L . We let the perfect functioning level M equal 4 and let the set of states of all components be $\{0, 2, 4\}$. For A_1, A_2 and A_3 these states are interpreted as

- 0: The generator cannot supply any power.
- 2: The generator can supply maximum 25 MW power.
- 4: The generator can supply maximum 50 MW power.

Note that as an approximation we have chosen to describe supply capacity of the generators using a discrete scale of three points. The supply capacity is not a measure of the actual amount of power delivered at a fixed point of time.

The control unit U has the states

- 0: U will by mistake switch off the main generators A_1 and A_3 without switching on A_2 ;
- 2: U will not switch on A_2 when needed;
- 4: U is functioning perfectly.

Figure 1 Outline of an offshore electrical power generation system

4 Multistate Reliability Theory

The subsea cables L are actually assumed to be constructed as double cables transferring half of the power through each cable. This leads to the following states of L

- 0: No power is transferred.
- 2: 50% of the power is transferred.
- 4: 100% of the power is transferred.

Let us now for simplicity assume that the mechanism that distributes the power from A_2 to oilrig 1 or 2 is working perfectly, transferring excess power from A_2 to oilrig 2 if oilrig 1 is ensured a delivery corresponding to state 4. Now let $\phi(A_1, A_2, A_3, U, L)$ = the amount of power that can be supplied to oilrig 2. In addition to the states taken by A_1, A_2, A_3 , ϕ can also take the following states

- 1: The maximum amount of power that can be supplied is 12.5 MW.
- 3: The maximum amount of power that can be supplied is 37.5 MW.

Number the components A_1, A_2, A_3, U , and L successively as 1, 2, 3, 4, and 5. Then this leads to

$$\phi(\mathbf{x}) = I(x_4 > 0) \min(x_3 + \max(x_1 + x_2 I(x_4 = 4) - 4, 0)x_5/4, 4) \quad (10)$$

noting that $\max(x_1 + x_2 I(x_4 = 4) - 4, 0)$ is just the excess power from A_2 , which one tries to transfer to oilrig 2. This is obviously a MMS.

Masked Failure Data: Competing Risks

Introduction

The term **competing-risks problem** has come to encompass the study of any failure process in which there is more than one distinct cause or type of failure. Frequent reference is made to possible influences of competing failure types in studies reported in the industrial, engineering as well as clinical, epidemiologic, demographic, and basic science literature. In engineering applications, the causes or risks may signify either multiple modes of failure for a complex unit or multiple components or subsystems which comprise an entire system. Occurrence of a system failure is caused by the earliest onset of any of these component failures. In this respect, the framework is that of a system with components connected in series. An additional complication arises when the causes of failure for a subset of systems are only known to belong to certain subsets of all possible causes; this is generally referred to as the cause of failure being *masked*. Masking is often the manifestation of an attempt to expedite the process of repair by replacing the entire subset of components responsible for failure instead of further investigation toward identifying the specific cause for failure. In practice, one possibility is to carry out a second-stage analysis to uniquely determine the cause; however, statistical inference may be possible even when the cause of failure is masked for a subset of systems.

Examples of failure data obtained under competing risks are abundant in reliability applications in engineering as well as in biomedical applications. In a medical context, the causes of failure (a failure may indicate death or relapse or other time-to-event outcome) typically refer to various potential risk factors for a patient (or animal) observed in a biomedical study. For example, Basu *et al.* [1] consider the risks from breast cancer and heart disease as well as other causes for breast cancer patients.

The literature on competing risks spans the work of Berman [2] to very recent work including the 2006 special issue of (JSPI) Journal of Statistical Planning and Inference [3]; the latter contains a wealth of references. An excellent resource for statistical theory and analysis of competing risks is the book by

Crowder [4]. The more recent book by Pintilie [5] emphasizes practical application of competing-risks theory, mostly in biomedical applications. In engineering applications, Langseth and Lindqvist [6] considered an interesting application of competing-risks models in the repairable systems, whereas Bunea and Mazzuchi [7] studied **competing failure modes in accelerated life testing**. Sun and Tiwari [8] analyzed the failure times of small electric appliances that may fail due to two competing risk whereas Taylor [9] modeled the tensile strength of certain materials known to contain two or more flaw types.

Competing Risks (without masking)

The early approach to analysis of competing-risks data introduced conceptual or latent failure times [2, 10] T_j , $j = 1, \dots, K$, corresponding to time to failure from risks $j = 1, \dots, K$, with associated probability density function $f_j(t)$, marginal survival function $S_j(t) = 1 - F_j(t)$, and net hazard function $h_j(t) = f_j(t)/S_j(t)$. Thus T_j is the potential failure time from cause $C = j$ that would be observed if the possibility of failure from causes other than j were removed. The observed lifetime T is then taken to be $T = \min(T_1, \dots, T_K)$. Let $S(t) = P(T > t)$ be the survival function for the observed lifetime T ; under the assumption that the potential failure times $T_1, \dots, T_K$ from the K competing risks are independent we have $S(t) = \prod_{j=1}^K S_j(t)$. The observation triplet is (T, C, δ) where C is the cause of failure and δ is the censoring indicator. The likelihood for an observation at time t can be expressed as

$$L(t, \delta = 0) = S(t) \text{ for a censored case} \quad (1)$$

$$\begin{aligned} L(t, C = j, \delta = 1) &= f_j(t) \prod_{l \neq j} S_l(t) \\ &= S(t) h_j(t) \text{ if cause is} \\ &\quad \text{identified as } C = j \end{aligned} \quad (2)$$

$$\begin{aligned} L(t, C \in \mathcal{C}, \delta = 1) &= \sum_{j \in \mathcal{C}} f_j(t) \prod_{l \neq j} S_l(t) \\ &= S(t) \sum_{j \in \mathcal{C}} h_j(t) \end{aligned} \quad (3)$$

where the last expression applies when the cause of failure is masked and is narrowed down to a subset $\mathcal{C}$

2 Masked Failure Data: Competing Risks

of $\{1, \dots, K\}$. This construction, of course, assumes independence of the K competing risks.

The random variable T_j used in the latent formulation is often referred to as the *potential failure time* since it represents the time to failure of the system when all other risks except the j th risk are removed from the system. The usefulness and interpretability of this model have been the subjects of debate [11, 12] since in most cases, it is either not feasible or physically impossible to remove all other risks from the system. The alternative cause-specific hazard formulation [11–13] is based on the joint distribution of the observed survival time T and cause of failure C . In particular, let $S(j, t) = P(C = j, T > t)$ be a “subsurvival” function with $S(t) = \sum_{j=1}^K S(j, t)$ denoting the marginal survival function of T . The corresponding subdensity function is denoted as $f(j, t)$. The cause-specific or subhazard function

$$\begin{aligned} h(j, t) &= \lim_{\varepsilon \rightarrow 0} \frac{P(C = j, T \leq t + \varepsilon | T > t)}{\varepsilon} \\ &= \frac{f(j, t)}{S(t)} \end{aligned} \quad (4)$$

is the instantaneous failure rate from cause j at time t after surviving from all risks $1, \dots, K$ up to time t . The cause-specific subhazard functions $h(j, t)$ are thus defined in terms of the joint distribution of the observed time and cause of failure (T, C) and constitute the basis of the cause-specific approach. The overall hazard from all risks combined is $h(t) = \sum_{j=1}^K h(j, t)$. The marginal survival can be written in term of the cause-specific hazards as $S(t) = \exp\left[-\sum \int_0^t h(j, s) ds\right]$ and each of the likelihood terms in equations (1–3) can be reexpressed by replacing the net hazard $h_j(t)$ with the cause-specific subhazard $h(j, t)$. The cumulative incidence function is defined as

$$\begin{aligned} P(T < t, J = j) &= \int_0^t f(j, u) du \\ &= \int_0^t h(j, u) S(u) du \end{aligned} \quad (5)$$

and may serve as a useful descriptive device [13, 14].

The book by Crowder [4] contains detailed comparison of the latent and the cause-specific approaches. Under the assumption of independence of the potential failure times $T_1, \dots, T_K$, the net hazard $h_j(t)$ and the cause-specific hazard $h(j, t)$ are identical (see Crowder [4] and Kalbfleisch and Prentice [12]), and the latent and cause-specific approaches lead to identical statistical inference. Independence assumes that the time of failure from cause j under one set of study conditions in which all K causes are operative is precisely the same as under an altered set of conditions in which all causes except the j th have been removed. However, the elimination of certain risks may well alter the hazards from other causes making the independence assumption of questionable validity (see Lagakos [15]). In addition, the all-too-known identifiability problem [16–20] entails that given a competing-risks model with a specific joint survivor function $\bar{F}(t_1, \dots, t_K)$ and arbitrary dependence between $T_1, \dots, T_K$, there exists a different joint survivor function in which $T_1, \dots, T_K$ are independent such that both models reproduce the same set of subsurvival functions $S(j, t)$. In particular, one cannot distinguish between the dependent model and the proxy independent model on the basis of observations on (C, T) alone. In fact, each such a model has a whole class of proxy models (not necessarily independent). Crowder [19] has extended this result to show that (under mild conditions) there exist infinitely many proxy joint survivor functions which will reproduce both the set of subsurvival functions $S(j, t)$ as well as the set of marginal survival functions $S_j(t)$, $j = 1, \dots, K$. Identifiability, however, can be regained when covariates are present. Heckman and Honore [21] showed that when there are explanatory variables in the model, identification of the joint survivor function $\bar{F}(t_1, \dots, t_K)$ is possible from the subsurvivor functions within a certain framework. Slud [22] proved a result of similar spirit under a different setup.

Moeschberger and Klein [23] provided a thorough review of analytic approaches for handling competing-risks data when the independence assumption is suspect. One approach is to assume a parametric joint distribution for the latent lifetimes T_j , $j = 1, \dots, K$. Parametric models are common in reliability applications and the identifiability problem is much less pervasive here (as opposed to non- or semiparametric models, which are more popular

in biomedical applications). Moeschberger [24] suggested using multivariate Weibull and normal distributions for the joint distribution of the latent lifetimes $(T_1, \dots, T_K)$. Basu and Klein [25] established that there is no identifiability problem in this setting. Basu and Ghosh [26, 27] demonstrated that many parametric distributions, including the Marshall–Olkin and the Gumbel distribution, are identifiable (up to a permutation) from (T, C) , the time and the cause.

As we noted before, the assumption of independence of the potential failure times $T_1, \dots, T_K$ implies that the cause-specific hazard $h(j, t)$ and the net hazard $h_j(t)$ are the same for all j and all $t > 0$. The latter equality $h(j, t) = h_j(t)$, $\forall j, t$ is known as the *Makeham assumption* [4]. While independence implies the Makeham condition, Gail [28] showed that the Makeham condition, in turn, implies that the subsurvival functions $S(j, t)$ determine the marginal survival functions $S_j(t)$. This implies $\bar{F}(t, t, \dots, t) = \prod_{j=1}^K S_j(t)$ or “independence on the diagonal”, but rather interestingly, the Makeham assumption may not imply independence (see William and Lagakos [29], and Crowder [4, 19]).

Competing Risks for Masked Data

Masking refers to the case when the causes of failure for a subset of systems are not exactly identified, but instead, have been narrowed down to subsets of $\{1, \dots, K\}$. Dinse [30] and Kodell and Chen [31] considered bioassays for animal carcinogenicity where masking arises owing to the disagreement on the reliability of cause of death information. They focused on nonparametric estimation of survival functions associated with the cause of interest as well as the other causes. Racine-Poon and Hoel [32] formally accounted for the uncertainty in diagnosing the exact cause of death by assigning a score on the diagnostic probability being correct. Dinse [33] obtained nonparametric maximum-likelihood estimates (MLEs) of cause-specific hazards in the setting of two competing risks and indicated a generalization to the multirisk case. Dinse [34] developed nonparametric estimation of the incidence rate. Lagakos and Louis [35] investigated various nonparametric tests for comparing difference in survival functions for two groups under masking. Goetghebeur and Ryan [36] derived a modified log-rank test for comparing the survival of two populations that was later modified by Dewanji [37]. Goetghebeur and Ryan [38]

developed proportional hazards structure in the context of two competing risks under the assumption that the baseline hazards for the two competing risks are proportional. Lu and Tsiatis [39] utilized multiple imputations to generalize this to the case when the baselines are not proportional. Flehinger *et al.* [40] proposed maximum-likelihood estimation under a similar model. Dewanji and SenGupta [41] developed an **EM algorithm** in the setting of masked but grouped survival data. Lu and Tsiatis [42] compared the two partial-likelihood approaches in masked data.

The parametric models are typically considered in engineering applications and are mostly based on the latent lifetime approach. One of the earliest parametric models was proposed by Miyakawa [43], who derived closed-form estimates for the case of two competing risks, each following exponential failure time distribution. In the same exponential framework, Usher and Hodgson [44] and Lin *et al.* [45] presented iterative algorithms for obtaining maximum-likelihood estimators when three competing risks are present. Guess *et al.* [46] presented a general framework that included an arbitrary number of competing risks. They introduced the term *minimum random subset* (MRS) to denote the subset $\mathcal{C}$ of the causes $\{1, \dots, K\}$ to which the cause of failure can be narrowed down. They also noticed that the likelihood term in equations (1–3) for the masked case actually contains additional terms involving the masking probabilities $Q(\mathcal{C}|C = j, t)$ and is given by

$$L(t, C \in \mathcal{C}, \delta = 1) = S(t) \sum_{j \in \mathcal{C}} \{h_j(t) Q(\mathcal{C}|C = j, t)\} \quad (6)$$

where the masking probabilities are defined as

$$Q(\mathcal{C}|C = j, t) = P(\text{cause is masked in subset } \mathcal{C} | C = j, t) \quad (7)$$

As noted by Flehinger *et al.* [40, 47], Craiu and Reiser [48], Craiu and Lee [49], and Craiu and Duchesne [50], the diagnostic probabilities

$$\pi(C = j|\mathcal{C}, t) = P(\text{actual failure due to cause } j | \text{cause masked in } \mathcal{C}, t) \quad (8)$$

which can be obtained from $Q(\mathcal{C}|C = j, t)$ and the likelihood model *via* Bayes rule are of interest. Guess *et al.* [46] described two “noninformative masking”

and “symmetry” conditions under which one can ignore the $Q(C|C = j, t)$ terms and proceed with likelihood inference. Guess *et al.* [46] and Lin *et al.* [45] cited industrial examples where it is reasonable to assume that these conditions hold. Similar symmetry conditions are assumed in Schäbe’s [51] and Goetghebeur and Ryan’s [38] semiparametric formulations. Lin and Guess [52] and Guttman *et al.* [53] use a proportionality assumption to meet the symmetry condition. Flehinger *et al.* [40] consider an interesting case when further data are available from second-stage autopsy on a subset of masked units. Craiu and Duchesne [50] and Craiu and Reiser [48] used EM-based methods to model and analyze these masking probabilities. Craiu and Lee [49] developed model selection for these models, whereas Craiu and Duchesne [54] compared the performances of EM and Bayesian data augmentation methods in this scenario. Sen *et al.* [55] provided a recent review of competing-risks analysis for masked data. Mukhopadhyay [56] obtained (MLEs) and bootstrap estimates of these masking probabilities in a general setting and established consistency and as well asymptotic normality of the MLEs under suitable regularity conditions. Kuo and Yang [57] developed different models for the masking probabilities and described Bayesian analysis of these models using Gibbs sampling methods. Mukhopadhyay and Basu [58] described a general Bayesian model for the masking probabilities; the details of this model is discussed in the next section.

Bayesian Approaches

Bayesian analysis of masked competing risks has been mostly limited to parametric models and the latent failure time approach, but see Craiu and Duchesne [54]. Mukhopadhyay and Basu [59], in one of the early Bayesian works, assumed that the component net survival distributions are exponential and obtain closed-form Bayesian estimates under a Dirichlet prior. Reiser *et al.* [60] considered two independent latent risks following exponential distributions, derived closed-form Bayes estimators for a noninformative Jeffreys’ prior, and showed that they are identical to the corresponding MLEs. Other prior choices under exponential lifetimes are discussed in Lin *et al.* [61] and Mukhopadhyay and Basu [62]. Guttman *et al.* [53] developed Bayesian analysis relaxing the symmetry condition for two competing

risks with associated exponential net survival distributions. Berger and Sun [63], Mukhopadhyay and Basu [62], and Basu *et al.* [64] considered the case of arbitrary number of competing risks where the latent failure time of each risk follows a Weibull distribution. While Mukhopadhyay and Basu [62] provided an EM algorithm, Basu *et al.* [64] used data augmentation and Gibbs sampling in the Bayesian analysis. Basu *et al.* [65] and Sen *et al.* [55] provided a general framework for parametric Bayesian analysis which encompasses location-scale and log-location-scale distributions. They used Markov chain sampling for the posterior analysis where they introduced latent variables C_i to augment the causes of failure for the masked cases. Basu *et al.* [65] also considered the case of interval censoring (when, instead of actually observing the time to event, events are only known to occur within a specified interval), applied these Bayesian parametric models in two engineering applications and provided Bayesian estimates of the diagnostic probability for the masked cases. They further compared different parametric models by Bayes factors and provide model diagnostics using the cross-validated predictive approach.

Mukhopadhyay and Basu [58] described a general approach for Bayesian analysis with the masking probabilities $Q(C|C = j, t)$. Suppose that $Q(C|C = j, t) = Q(C|C = j)$ are free of t and let $\mathcal{F}_j$ denote the collection of all subsets of $\{1, \dots, K\}$ which includes j . We then have $\sum \{Q(C|C = j) : C \in \mathcal{F}_j\} = 1$ and Mukhopadhyay and Basu [58] assigned Dirichlet distribution prior on this simplex. Such a prior specification, in fact, produces a conditionally conjugate structure, which lead to a straightforward updating scheme for the masking probabilities within the Markov chain sampling. Mukhopadhyay and Basu [58] obtained Bayesian estimates of both the masking and the diagnostic probabilities in the data example. As we noted before, Kuo and Yang [57] also considered Bayesian analysis of the masking probabilities, whereas Craiu and Duchesne [54] compared Bayesian data augmentation with the EM algorithm.

Applications

Crowder [4] and Nelson [66] listed a collection of data sets from engineering applications involving competing risks. They include data on breaking strength of wire connections (2 possible causes of

failure), data on failure time of electric appliances (many possible causes), data from accelerated life tests of industrial heaters and data from low-cycle fatigue test of a superalloy. Langseth and Lindqvist [6] analyzed an interesting dataset from the Off-shore Reliability Database which involved competing risks in repairable systems. Flehinger *et al.* [47] listed data of 172 failure times observed over a period of 4 years during which 10 000 computer hard drives were monitored. There are three possible causes of failure; but they are masked for some of the systems in either $\mathcal{C} = \{1, 3\}$ or $\mathcal{C} = \{1, 2, 3\}$. These data were also analyzed by Craiu and Reiser [48]. Basu *et al.* [65] analyzed data from a 10 000-hr field trial of 4993 circuit-boards reported in Chan and Meeker [67] and considered “infant mortality” and wearout as two competing risks. There is an interval when both modes are simultaneously operative and the cause for a failure within this interval is considered as masked. Reiser *et al.* [60], Basu *et al.* [64, 65], Mukhopadhyay [56], and Mukhopadhyay and Basu [58] analyzed time-to-failure data of computer component systems where failure was attributed to malfunctioning of one of the three components. Out of a total of eight system failures, the causes of three were masked. In addition, 676 systems were progressively censored at various times and this heavy censoring poses an additional challenge to statistical analysis. Basu *et al.* [65] analyzed these data using different parametric models and noted that due to the limited information in the data, the Bayesian inference is expected to depend on the assumed model and prior. Mukhopadhyay [56] and Mukhopadhyay and Basu [58] analyzed these data using a general model for the masking probabilities $Q(\mathcal{C}|C = j)$. The maximum-likelihood analysis in Mukhopadhyay [56], for example, estimate that if the true cause of failure is $C = 3$, then the probability that the cause will be identified $\hat{Q}(3|C = 3) \approx 0.5$, the probability that the cause will be masked in $\{2, 3\}$ is $\hat{Q}(\{2, 3\}|C = 3) \approx 0.5$, whereas $\hat{Q}(\{1, 3\}|C = 3)$ and $\hat{Q}(\{1, 2, 3\}|C = 3)$ are ≈ 0 . The Bayesian estimates in Mukhopadhyay and Basu [58], however, assign approximately 0.20 probability to each of $Q(\{1, 3\}|C = 3)$ and $Q(\{1, 2, 3\}|C = 3)$. The diagnostic probabilities $\pi(C = j|\mathcal{C})$ reported in Basu *et al.* [69] also differ from the estimates reported in Mukhopadhyay and Basu [58]. Such diversity in the results, however, are expected due to the limited information available in these data and the

diversity in the models used for analysis. Mukhopadhyay and Basu, for example, used noninformative priors whereas Basu *et al.* [65] argued for a rather informative prior.

In their review on analysis of masked data in competing risks, Sen *et al.* [55] cited dependent causes, symmetry assumption, and covariate inclusion as research areas that need further exploration. The recent literature has seen substantial progress in each of these areas. Identifiability concerns from competing risks are more pervasive in masked data (when some causes are not completely known); while individual results are scattered in the literature, we are not aware of a general result. The shortage in the availability of rich data from reliability applications is also often a deterrent to methodological development in this area.

Nonparametric and Semiparametric Bayesian Reliability Analysis

Introduction

Suppose that T is a nonnegative random variable denoting lifetime. We define the survival function at time t to be $S(t) = P(T > t) = 1 - F(t)$, where F is the cumulative distribution function (**cdf**). If T has density $f(t)$, the hazard rate function $r(t)$ at time t is given by $r(t) = \frac{f(t)}{S(t)}$. This gives the instantaneous failure rate at time t given survival just prior to time t . The corresponding cumulative hazard at time t is $R(t) = \int_0^t r(s) ds$. It is well known that $S(t) = \exp(-R(t))$. Hence, knowing any one of density, cdf, survival function, hazard rate function, or cumulative hazard function is equivalent for inference about the properties of the life distribution. Sometimes, the phrase “reliability function” is used to denote the survival function of a component or a system of components connected in some structure.

In reliability and survival analysis, it is often of interest to estimate the reliability of the system/component from the observed lifetime data. Suppose n components are put to test and $T_1, \dots, T_n$ are the corresponding lifetimes. If all $T_1, \dots, T_n$ are actually observed, we have complete data. Usually, however, some of the T_i 's are censored. Suppose that T_i and C_i are the lifetime and (right) censoring times, respectively, of the i th component. One observes $X_i = \min(T_i, C_i)$ and $\delta_i = I_{T_i \leq C_i}$. On the basis of observed data (X_i, δ_i) , $i = 1, \dots, n$, one would like to infer about the lifetime distribution as a whole.

No matter whether one has complete or censored data, a host of techniques have been developed for their analysis. They can be broadly classified as parametric and nonparametric approaches. The advantages of parametric methods are their simplicity in the sense that only a handful of parameters can be used to explain the behavior. For example, Kvam and Samaniego [1] used a parametric approach for analyzing the life-history data from an r -out-of- k system whereby the component lifetimes were assumed to be exponentially distributed. The unknown parameter was estimated using the maximum-likelihood method. However, as is well known, parametric

models impose certain structural restrictions and are less than optimal if one is unable to verify/justify the model assumptions. An alternative is to use nonparametric methods such as the ones used by Kvam and Samaniego [1] or Chen [2] in estimating **component reliability**.

In this article, we first review some nonparametric and semiparametric Bayesian methods available for the analysis of life-history data. The advantage of using Bayesian methods is the ability to incorporate prior information in the inferential procedure, and semiparametric models allow for partial specification of model structure through parameters. We then present a semiparametric Bayesian approach for estimating the component lifetime distribution on the basis of the system lifetime data, along with additional information (such as the censoring indicator and the number of failed components) for multiple k -out-of- n systems [3].

In the section titled “Nonparametric Methods”, we briefly review past work on the nonparametric Bayesian analysis for survival data. In the section titled “Semiparametric Method”, we present a theoretical development of a semiparametric procedure. Under “Sampling Procedure”, we briefly discuss the sampling procedure that will be used to implement the model. In the section titled “Illustration”, we present the results of a simulation study based on data from Chen [2]. Finally, in the last section, we close with some concluding remarks.

Nonparametric Methods

In Bayesian analysis, it is very important to have as close to correct a likelihood function as possible. Often, the standard parametric models are not rich enough to capture the uncertainty in the observed data. In such situations, nonparametric Bayesian methods provide a more flexible alternative. Nonparametric Bayesian methods in reliability can be broadly classified into three groups, depending on the quantity on which one places a prior distribution: prior on the class of all distributions, prior on the class of all hazard rates, and prior on the class of all cumulative hazards. In each case, the underlying distribution is assumed to be free of any parameters and the prior information is combined with life-history data to obtain the corresponding posterior. Owing to the nonparametric nature, the **prior distributions** are taken

2 Nonparametric and Semiparametric Bayesian Analysis

to be stochastic processes. We provide a brief review of the three methods in the following subsections. For a comprehensive review of various nonparametric methods of estimating the survival function, see Ferguson *et al.* [4]. Also see Sinha and Dey [5] and Singpurwalla [6] for a detailed discussion on nonparametric approaches to reliability **estimation**.

Prior on Distributions

Dirichlet processes, introduced by Ferguson [7] are one of the fundamental concepts in the nonparametric Bayesian analysis literature. A Dirichlet process can be used to provide a nonparametric prior for a distribution function.

Suppose that F is a cdf. We say that F has a Dirichlet process prior, i.e. $F \sim \mathcal{D}(M, F_0)$ if the following happens. For any partition $A_1 \cup A_2 \cup \dots \cup A_k = \mathfrak{R}$,

$$(F(A_1), F(A_2), \dots, F(A_k)) \sim \text{Dirichlet}(MF_0(A_1), MF_0(A_2), \dots, MF_0(A_k)) \quad (1)$$

where $\text{Dirichlet}(\alpha_1, \dots, \alpha_k)$ denotes a Dirichlet distribution with parameters $(\alpha_1, \dots, \alpha_k)$. See Wilks [8] for more on Dirichlet distribution. $M > 0$ is called the *precision parameter* and F_0 is called the *baseline distribution*. F_0 can be thought of as the “average value” of F and M as the amount of “concentration” of F around F_0 . A high value of M signifies that F is very close to F_0 and a low value of M signifies large dispersion around F_0 . However, see Sethuraman and Tiwari [9] for another interpretation of small values of M .

Ferguson [7] showed that if $\theta|F \sim F$ and $F \sim \mathcal{D}(M, F_0)$, then $F|\theta \sim \frac{1}{M+1}[MF_0 + \delta_\theta]$. Here, δ_θ denotes the degenerate part of the distribution at a specific value of θ . Repeated application of this result shows that if $T_1, \dots, T_n$ are observations generated by F , and F has a Dirichlet process prior $\mathcal{D}(M, F_0)$, the Bayes estimator of F is

$$\hat{F}(t) = \frac{M}{M+n}F_0(t) + \frac{1}{M+n}F_n(t) \quad (2)$$

where $F_n(t)$ is the empirical distribution function of the sample.

The above requires complete information about the lifetimes (i.e., no censoring). Susarla and Van Ryzin [10] developed the nonparametric Bayes estimator of the cdf in the presence of right censoring and assuming a Dirichlet process prior on the underlying distribution. Let $(X_i, \delta_i), i = 1, \dots, n$ be the observed data with $X_i = \min(T_i, C_i)$ and $\delta_i = I_{T_i \leq C_i}$. Let $u_1 < \dots < u_k$ be the distinct values among $X_1, \dots, X_n$ and λ_j be the number of censored observations at u_j . Let $k(t)$ be the number of u_j 's that are less than or equal to u_k and h_k be the number greater than u_k . Then, the Bayes estimator of the survival function under squared error loss is given by

$$\frac{M(1 - F_0(t)) + h_k(t)}{M + n} \prod_{j=1}^{k(t)} \frac{M(1 - F_0(u_j)) + h_j + \lambda_j}{M(1 - F_0(u_j)) + h_j} \quad (3)$$

This estimator reduces to the Kaplan–Meier estimator as $M \rightarrow 0$, and under no censoring, reduces to the estimator given earlier.

Dirichlet processes give rise to distributions as priors that are discrete with probability one. In addition, the corresponding Bayes estimator gets complicated for right-censored data. To avoid these difficulties, one may use neutral-to-the-right (NTR) priors. A random distribution function F on the real line is said to be NTR if for every m and $t_1 < t_2 < \dots < t_m$, there exist independent random variables $V_1, \dots, V_m$ such that $(1 - F(t_1), \dots, 1 - F(t_m))$ has the same distribution as $(V_1, V_1 V_2, \dots, \prod_{i=1}^m V_i)$. Doksum [11] and Ferguson and Phadia [12] show that if $X_1, \dots, X_n$ is a sample from F and F is NTR, then the posterior distribution of F given $X_1, \dots, X_n$ is also NTR. It turns out that the censored case is simpler to treat than the uncensored case. The implementation of the results for practical applications gets cumbersome. Damien *et al.* [13] and Walker and Damien [14] have proposed simulation-based approaches for a full Bayesian analysis involving NTR processes.

Prior on Hazard Functions

An alternative approach is to put a nonparametric prior on the class of all hazard functions. Suppose we partition the time axis into $(k+1)$ intervals $0 < t_1 < \dots < t_k < \infty$. Let $p_1 = F(t_1)$, $p_i =$

$F(t_i) - F(t_{i-1})$, $i = 2, \dots, k$. Note that $F(0) = 0$ and $F(\infty) = 1$. Define $Z_1 = p_1$, $Z_i = p_i / (1 - p_1 - \dots - p_{i-1})$ for $i = 2, \dots, k$. Note that Z_i is the failure rate over the interval $[t_{i-1}, t_i)$ and $(Z_1, \dots, Z_k)$ gives the piecewise constant hazard function over $[0, t_k)$. Let n_i denote the number of failures in the interval $[t_{i-1}, t_i)$, $\mathbf{p} = (p_1, \dots, p_k)$ and $\mathbf{d} = (n_1, \dots, n_{k+1})$. The observed data is given by $\mathbf{d}$.

In such a scenario, one may assume that the prior distribution of the Z_i 's is independent, $\beta(v_{1i}, v_{2i})$. This results in a generalized Dirichlet prior for $\mathbf{p}$ given by the probability function

$$f(p_1, \dots, p_k) = \prod_{i=1}^k \frac{\Gamma(v_{1i} + v_{2i})}{\Gamma(v_{1i})\Gamma(v_{2i})} p_i^{v_{1i}-1} \times (1 - p_1 - \dots - p_k)^{\gamma_i} \quad (4)$$

where $\gamma_i = v_{2i} - v_{1,i+1} - v_{2,i+1}$ for $i = 1, \dots, k-1$ and $\gamma_k = v_{2k} - 1$. See Basu and Tiwari [15] for the special case when the generalized Dirichlet prior for $\mathbf{p}$ reduces to the Dirichlet prior. Given the observed count data $\mathbf{d}$, the posterior of the piecewise hazards turns out also to be generalized Dirichlet. Lochner [16] and Tiwari and Rao [17] further discuss the use of this approach to estimate F . This method has several disadvantages. First, it uses count data, leading to loss of information by not using the actual failure times. Second, the inferential conclusions depend on whether the cells are combined at the prior or at the posterior stage. In addition, one needs an excessive number of parameters to specify the generalized Dirichlet distribution. See also Wilks [8] for more on generalized Dirichlet distributions.

The above procedure cannot account for any structural pattern in the hazard rate function. Padgett and Wei [18] and Arjas and Gasbarra [19] take the prior on the hazard rate function to be a **Poisson process** with constant jump size. Mazzuchi and Singpurwalla [20] take the prior on hazard rate function to be ordered Dirichlet. The former ensures that the hazard rate function is nondecreasing and the latter ensures that it is monotone.

Dykstra and Laud [21] introduce an extended gamma process and use it to model the prior distribution of a nondecreasing hazard rate process. They show that when $t_1, \dots, t_n$ are the right-censoring times of n observations and $\Gamma(a(s), \beta(s))$ is the prior on the hazard rate process; the posterior on

the hazard rate process is also an extended gamma process $\Gamma(a(s), \hat{\beta}(s))$ where

$$\hat{\beta}(s) = \frac{\beta(s)}{1 + \beta(s) \sum_{i=1}^n (t_i - s)^+} \quad (5)$$

with $a^+ = \max(a, 0)$. When one observes the actual failure times $t_1, \dots, t_n$, the resulting posterior hazard rate is a mixture of extended gamma processes, which is complicated to calculate. Laud *et al.* [22] approximate this posterior by approximating its random independent increments *via* a Gibbs sampler. Once the posterior hazard rate process is obtained, the corresponding survival function is given by

$$P(T \geq t) = \exp \left[- \int_0^t \log(1 + \hat{\beta}(s)(t - s)) da(s) \right] \quad (6)$$

Other methods of specifying the prior on hazard rates include use of Markov beta and Markov gamma processes considered by Nieto-Barajas and Walker [23]. See also Tiwari and Rao [17], Tiwari and Jammalamadaka [24], and Tiwari and Kumar [25].

Prior on Cumulative Hazard

An alternative to putting a prior on the hazard rate function is to put a prior on the cumulative hazard function. This is particularly attractive especially when there is no density, since the cumulative hazard still exists in such situations. Kalbfleisch [26] proposed using a gamma process as a prior for the cumulative hazard function $R(t)$. Take any partition $0 \equiv t_0 < t_1 < t_2 < \dots < t_{k-1} < t_k \equiv \infty$, of the time points and define $r_i = \log(1 - Z_i)$ where $Z_i = P(T \in [t_{i-1}, t_i) | T \geq t_{i-1})$ is the hazard rate over the interval $[t_{i-1}, t_i)$. Assume that r_i 's are independent gamma random variables with shape $\alpha_i - \alpha_{i-1}$ and scale c , where $\alpha_i = cR^*(t_i)$ and $R^*(t)$ is interpreted as the best guess of $R(t)$. c is the measure of strength of conviction about the guess and large values indicate a strong conviction.

Given n failure times $\tau_1, \dots, \tau_n$, the posterior cumulative hazard will be a process with independent increments. Kalbfleisch [26] has shown that the posterior cumulative hazard has an increment at τ_i

4 Nonparametric and Semiparametric Bayesian Analysis

which is given by a density $A(c + A_i, c + A_{i+1})$ at u , where $A_i = n - i$ and $A(a, b)$ is of the form

$$\frac{\exp(-bu) - \exp(au)}{u \log(a/b)}$$

Between τ_{i-1} and τ_i , the increments are prescribed by a gamma process with shape function $cR^*(\cdot)$ and scale $c + A_i$. The survival function is recovered either by simulation or by approximation using expected value of the process.

The above formulation suffers from some difficulties. First, there is a lack of intuition regarding the assumption of gamma distribution on r_i . Second, the independent increments property of $R(t)$ may not be meaningful, since under aging and wear, the successive Z_i 's would be judged to be increasing. Finally, presence of ties in the failure time data presents problems in the model fitting.

A different model was proposed by Hjort [27] to model the randomness in the cumulative hazard rate. Suppose R has a beta process prior with parameters $c(\cdot)$ and $R_0(\cdot)$. The posterior of R given life-history data $(X_1, \delta_1), \dots, (X_n, \delta_n)$ is also a beta process of the form

$$R|\text{data} \sim \beta \left[c(\cdot) + Y(\cdot), \int_0^{\cdot} \frac{c \, dR_0 + dN}{c + Y} \right] \quad (7)$$

where

$$N(t) = \sum_{i=1}^n I(X_i \leq t, \delta_i = 1) \quad (8)$$

and

$$Y(t) = \sum_{i=1}^n I(X_i \geq t) \quad (9)$$

are two counting processes derived from the data. The Bayes estimator of $R(t)$ under squared error loss is

$$\hat{R}(t) = \int_0^t \frac{c \, dR_0 + dN}{c + Y} \quad (10)$$

and the corresponding estimator of F is

$$\hat{F}(t) = 1 - \prod_{[0,t]} \left[1 - \frac{c \, dR_0 + dN}{c + Y} \right] \quad (11)$$

As $c(\cdot)$ decreases to zero, $\hat{F}$ tends to the Kaplan–Meier estimator.

Semiparametric Method

Often, it may be necessary to impose certain structural restrictions on the underlying survival/reliability model to aid in the physical understanding and interpretation, all the while maintaining considerable generality. In such situations, one may decide to use semiparametric models, whereby parts of the model are parametric (reflecting the desired structural restriction) and the remainder nonparametric. An example of this is the **Cox** model, introduced by Cox [28]. To perform Bayesian analysis, the nonparametric part is assumed to be a realization of a stochastic process. As before in the nonparametric Bayesian analysis case, one can put nonparametric priors on the hazard rates. Different methods have been discussed in Sinha and Dey [5] for dealing with these models.

Recently, Merrick *et al.* [29] developed a semiparametric Bayesian proportional hazards model for reliability and maintenance of machine tools. Their proposed model uses a mixture of Dirichlet process (MDP) prior for the baseline failure rate in the proportional hazards model. Such priors were introduced by Antoniak [30] and have been popularized by various authors such as MacEachern [31] and West *et al.* [32]. Another application of Bayesian semiparametric models in reliability is presented in Merrick *et al.* [33], where the authors use a proportional intensities model and present a semiparametric Bayesian approach for nonhomogeneous Poisson processes. Apart from the above, we were unable to find Bayesian semiparametric models in the context of reliability analysis. This emphasizes the fact that while Bayesian semiparametric models have been popular in survival analysis, they have not been as popular in (engineering) reliability analysis. Below, we present a new model to estimate component reliability using system reliability data from multiple r -out-of- k systems.

In industrial and biological problems, one often has a multicomponent system (consisting of, say, k components) and observes the time of system failure. Owing to the system architecture, failure of the system occurs if and only if at least a certain number of components (say, r) fail. For example, a liquid crystal display (LCD) may be said to correctly function when at least 80% of its pixels function properly. Such a system is called an r -out-of- k system, special cases of which are a series system

($r = 1$) and a parallel system ($r = k$). r -out-of- k systems have been well studied in the reliability context and are a favorite way of increasing system **redundancy**. See Hoyland and Rausand [34] for more details on r -out-of- k systems and associated examples.

Suppose that we have an r -out-of- k system that consists of k components with identical life distributions that act independent of each other. Assume that the component life distribution is given by $F(\cdot|\theta)$ where θ is an unknown p -dimensional parameter. Suppose that T is the system failure time and C is the censoring time. We observe $X = T \wedge C$ and $\delta = I(X = T)$, the censoring indicator. When $\delta = 1$, X is distributed as the r th-order statistic based on a sample of size k from $F(\cdot|\theta)$. When $\delta = 0$ (i.e., the system was alive and censored at X), we may or may not have information on the number of components $s(< r)$ in the system that have failed. Let $\gamma = 1$ indicate that s is observed and $\gamma = 0$ indicate that s is unobserved. Assuming that $F(\cdot|\theta)$ is absolutely continuous with respect to the Lebesgue measure, the likelihood contribution of the system is

$$L(\theta) = \left[r \binom{k}{r} F^{r-1}(x|\theta) f(x|\theta) \{1 - F(x|\theta)\}^{k-r} \right]^\delta \left[\binom{k}{s} F^s(x|\theta) \{1 - F(x|\theta)\}^{k-s} \right]^{(1-\delta)\gamma} \left[\sum_{s=0}^{r-1} \binom{k}{s} F^s(x|\theta) \{1 - F(x|\theta)\}^{k-s} \right]^{(1-\delta)(1-\gamma)} \quad (12)$$

When $\delta = 1$, we take $\gamma = 1$ and $s = r$.

Suppose that for $i = 1, \dots, n$, we have m_i copies of an r_i -out-of- k_i system. The m_i copies are assumed to be independently distributed with the same component distribution $F(\cdot|\theta_i)$. For $i \neq j$, the systems are also assumed to be conditionally independent of each other and the parameters θ_i and θ_j may or may not be equal.

The resulting data X is presented in Table 1.

Denoting $\theta_n = (\theta_1, \dots, \theta_n)$, the likelihood is given by

$$L(\theta_n|X) = \prod_{i=1}^n \prod_{j=1}^{m_i} \left[r_i \binom{k_i}{r_i} \{F(x_{ij}|\theta_i)\}^{r_i-1} f(x_{ij}|\theta_i) \times \{1 - F(x_{ij}|\theta_i)\}^{k_i-r_i} \right]^{\delta_{ij}} \times \left[\binom{k_i}{s_{ij}} \{F(x_{ij}|\theta_i)\}^{s_{ij}} \{1 - F(x_{ij}|\theta_i)\}^{k_i-s_{ij}} \right]^{(1-\delta_{ij})\gamma_{ij}} \times \left[\sum_{s=0}^{r_i-1} \binom{k_i}{s} \{F(x_{ij}|\theta_i)\}^s \{1 - F(x_{ij}|\theta_i)\}^{k_i-s} \right]^{(1-\delta_{ij})(1-\gamma_{ij})} \quad (13)$$

We assume that the θ_i 's are independent and identically distributed from a distribution G with a Dirichlet process prior having baseline distribution G_0 and precision M . Hence the prior distribution of $\theta_1, \dots, \theta_n$ assuming M and G_0 are known is given by (see Antoniak [30], Blackwell and MacQueen [35]):

$$\pi(\theta_n) = \prod_{i=1}^n \left[\frac{M G_0(d\theta_i) + \sum_{j < i} \delta_{\theta_j}(d\theta_i)}{M + i - 1} \right] \quad (14)$$

As mentioned earlier, under the Dirichlet process setup, some of the system parameters θ_i may be identical. This is a reflection of the fact that some of the systems may be built using components from the same manufacturer and thus would have similar behavior.

Our goal will be to estimate the reliability of a component using the predictive approach. Assuming that a future system has a parameter θ_{n+1} and that

Table 1 Failure time data from several r -out-of- k systems

System	r	k	Observations		
1	r_1	k_1	$(X_{11}, \delta_{11}, \gamma_{11}, s_{11})$	$\dots$	$(X_{1m_1}, \delta_{1m_1}, \gamma_{1m_1}, s_{1m_1})$
2	r_2	k_2	$(X_{21}, \delta_{21}, \gamma_{21}, s_{21})$	$\dots$	$(X_{2m_2}, \delta_{2m_2}, \gamma_{2m_2}, s_{2m_2})$
$\dots$	$\dots$	$\dots$	$\dots$	$\dots$	$\dots$
n	r_n	k_n	$(X_{n1}, \delta_{n1}, \gamma_{n1}, s_{n1})$	$\dots$	$(X_{nm_n}, \delta_{nm_n}, \gamma_{nm_n}, s_{nm_n})$

X_{n+1} is the lifetime of a component of the system, we want

$$\begin{aligned}
S(x) &= P(X_{n+1} > x | \mathbf{X}) \\
&= \int P(X_{n+1} > x | \theta_{n+1}, \mathbf{X}, \boldsymbol{\theta}_n) \\
&\quad \times f(\theta_{n+1} | \boldsymbol{\theta}_n, \mathbf{X}) f(\boldsymbol{\theta}_n | \mathbf{X}) d\boldsymbol{\theta}_{n+1} \\
&= \int \bar{F}_{n+1}(x | \theta_{n+1}) \frac{1}{M+n} [MG_0(d\theta_{n+1}) \\
&\quad + \sum_{j=1}^n \delta_{\theta_j}(d\theta_{n+1})] f(\boldsymbol{\theta}_n | \mathbf{X}_n) d\boldsymbol{\theta}_n \\
&= \frac{1}{M+n} \int [M \int \bar{F}(x | \theta) G_0(d\theta) \\
&\quad + \sum_{j=1}^n \bar{F}(x | \theta_j)] f(\boldsymbol{\theta}_n | \mathbf{X}) d\boldsymbol{\theta}_n \quad (15)
\end{aligned}$$

Note that the complicated nature of the likelihood precludes any conjugate choice of baseline prior to simplify the posterior distribution calculations.

Ferguson [36], Kuo [37], and Tiwari and Kumar [25] have used this type of mixture approach for estimating parameters such as density function and reliability. We will use the Gibbs sampler to sample from the posterior and draw inferences. The Gibbs sampler is difficult to implement as is, since the likelihood contributions involve calculations of the cdf, the **probability density function**, and/or sums involving them. While several algorithms have been proposed to deal with such non-conjugate setups for sampling from the posterior in an MDP setting [38], they are computationally intensive.

The problem arises because we have several unobserved lifetimes, essentially making data incomplete. Here, we introduce a data-augmentation technique (see Tanner and Wong [39], Tanner [40]) whereby the observed data are augmented to get the “complete” data $\tilde{\mathbf{X}} = \{X_{ijl}\}$, i.e. the exact failure times of all the components in a system. The likelihood based on the augmented data can then be written as

$$\tilde{L}(\boldsymbol{\theta}_n | \tilde{\mathbf{X}}) = \prod_{i=1}^n \prod_{j=1}^{m_i} \prod_{l=1}^{k_i} f(x_{ijl} | \theta_i) \quad (16)$$

Similar techniques were also used in Kim and Arnold [41]. This simplifies calculations by taking advantage of the conjugate structure of the likelihood and the baseline prior. Note that the posterior distribution of the number of failed components s_{ij} for systems in which such data are missing arises naturally and can be interpreted as the posterior based on a uniform prior on $\{0, \dots, k_i\}$.

Sampling Procedure

1. Generate a set of starting values of $\theta_1, \dots, \theta_n$.
2. If $\delta_{ij} = \gamma_{ij} = 0$, sample s_{ij} from binomial($k_i, F(X_{ij} | \theta_i)$) truncated to $\{0, \dots, r_i - 1\}$.
3. If $\delta_{ij} = 1$, generate $\{X_{ij(l)}\}_{l=1}^{r_i-1}$ as order statistics from

$$g_L(x | X_{ij}, \theta_i) = \frac{f(x | \theta_i)}{F(X_{ij} | \theta_i)}, \quad 0 < x < X_{ij} \quad (17)$$

Also generate $\{X_{ij(l)}\}_{l=r+1}^{k_i}$ as order statistics from

$$g_U(x | X_{ij}, \theta_i) = \frac{f(x | \theta_i)}{1 - F(X_{ij} | \theta_i)}, \quad X_{ij} < x < \infty \quad (18)$$

Also, set $X_{ij(r)} \equiv X_{ij}$.

Note that $g_L(\cdot | X_{ij}, \theta_i)$ is the density of observations from $F(\cdot | \theta_i)$ truncated above at X_{ij} . Similarly, $g_U(\cdot | X_{ij}, \theta_i)$ is the density for observations that are truncated below.

4. If $\delta_{ij} = 0$, generate $\{X_{ij(l)}\}_{l=1}^{s_{ij}}$ as order statistics from $g_L(\cdot | X_{ij}, \theta_i)$ and also generate $\{X_{ij(l)}\}_{l=s_{ij}+1}^{k_i}$ as order statistics from $g_U(\cdot | X_{ij}, \theta_i)$.
5. Having generated the “complete data” $\{X_{ijl}\}$, we update the θ ’s conditionally as

$$\begin{aligned}
\theta_i | \text{rest} &\sim \prod_{j=1}^{m_i} \prod_{l=1}^{k_i} f(X_{ijl} | \theta_i) \\
&\times \left[\frac{MG_0(d\theta_i) + \sum_{j \neq i} \delta_{\theta_j}(d\theta_i)}{M+n-1} \right] \quad (19)
\end{aligned}$$

This is done using the Gibbs sampler. Note that in the above expression, we need the exact failure times X_{ijl} , not the ordered values $X_{ij(l)}$. If the sufficient statistic does not depend on the ordering of the observations, one can replace the exact values by the ordered values. Such is the case, for example, when

one is interested in inferring the mean of a normal or the scale of a Weibull distribution.

6. Go back to 2 and repeat until convergence to the steady state.

Below, we give a special case for illustration:

Lognormal Distribution

If the component failure times are distributed as lognormal(μ, σ^2) ($LN(\mu, \sigma^2)$), we can generate samples from the truncated distributions given by $g_L(\cdot)$ and $g_U(\cdot)$ using

$$X_L = \exp \left[\mu + \sigma \Phi^{-1} \left(U \Phi \left(\frac{\log X - \mu}{\sigma} \right) \right) \right] \quad (20)$$

and

$$X_U = \exp \left[\mu + \sigma \Phi^{-1} \left(U + (1 - U) \Phi \left(\frac{\log X - \mu}{\sigma} \right) \right) \right] \quad (21)$$

where $U \sim U(0, 1)$. Note that the random variables X_L and X_U above are generated by inverting the cdf's corresponding to g_L and g_U , respectively.

In this case,

$$\prod_{j=1}^{m_i} \prod_{l=1}^{k_i} f(x_{ij(l)} | \theta_i) = \frac{1}{(2\pi\sigma^2)^{m_i k_i / 2}} \frac{1}{\prod_{j,l} x_{ij(l)}} \times \exp \left[-\frac{1}{2\sigma^2} \sum_{j,l} (\log x_{ij(l)} - \mu_i)^2 \right] \quad (22)$$

Note that $\sum_{j=1}^{m_i} \sum_{l=1}^{k_i} \log x_{ij(l)} = \sum_{j=1}^{m_i} \sum_{l=1}^{k_i} \log x_{ijl}$ is the sufficient statistic and is not order dependent.

Illustration

We used the system configuration given in Table 2 to generate our data [see 2].

To generate an observation on an r_i -out-of- k_i system, a simple random sample of size k_i is generated from F and another simple random sample of size k_i is generated from G . Let $u_{i(r_i)}$ and $v_{i(r_i)}$ be

Table 2 Configuration of several r -out-of- k systems

i	1	2	3	4	5	6
r_i	1	3	5	1	4	7
k_i	5	5	5	7	7	7
m_i	10	9	11	12	10	13

the r_i th-order statistics from the two samples, respectively. If $u_{i(r_i)} \leq v_{i(r_i)}$, the generated observation is taken as $(X_i, \delta_i, \gamma_i, s_i) = (u_{i(r_i)}, 1, 1, r_i)$. Otherwise, let r be the rank of the largest-order statistic from F that is smaller than $v_{i(r_i)}$. With 90% probability, the generated observation is taken as $(X_i, \delta_i, \gamma_i, s_i) = (v_{i(r_i)}, 0, 1, r)$ and with 10% probability, the generated observation is taken as $(X_i, \delta_i, \gamma_i, s_i) = (v_{i(r_i)}, 0, 0, 0)$. We used lognormal distribution with $\mu_{01} = 1$, $\sigma_{01} = 1$ as the F and a lognormal distribution with $\mu_{02} = \{0.8, 2.8\}$, $\sigma_{02} = 1$ as G . This procedure was seen to give rise to 68% censoring when $\mu_{02} = 0.8$ and about 0% censoring when $\mu_{02} = 2.8$. As indicated earlier, for a censored lifetime, the number of failed components was noted with probability 0.9 in each of the censoring schemes.

Once the dataset was generated according to the above procedure, we estimated the reliability of a single component $S(x)$ as outlined in equation (15). We assumed that the underlying population is $LN(\mu, 1)$ with $\mu \sim \mathcal{D}(M, G_0)$ and $G_0 \sim N(1, 1)$. We also assumed $M \sim \gamma(0.1, 0.1)$ and ran a full Bayesian approach. The updating of M was done along the lines of Escobar and West [42] and for improved mixing, the μ_i 's were updated using "Algorithm 3" in Neal [38]. The predictive reliability is based on 5000 runs of the Gibbs sampler with a thinning of 10, obtained after a **burn-in** of 5000 iterations. Convergence was ascertained using CODA [43]. The results are presented in Figure 1. The precision of the estimate is measured by RMSE (root mean square error), which is the RMSE of the estimate at selected points and is given in Table 3.

We see that as the percentage of censoring increases, the estimated values get farther away from

Table 3 Accuracy of the estimates based on data from various censoring schemes

μ_{02}	RMSE	Censoring proportion (%)
0.8	0.055	67.69
2.8	0.048	0

Figure 1 Estimated reliability of a component from the system configuration in Table 2 using different censoring distributions

the true values. In the case where $\mu_{02} = 0.8$, we also kept track of the true (but unobserved) number of component failures at the data generation stage and the estimated values at the simulation stage. The average number of failures turned out to be (0, 0, 2.18, 2.77, 5.70, 5.97), while the true values are (0, 0, 2, 1, 6, 6).

Conclusion

We have presented a brief overview of nonparametric and semiparametric Bayes methods in lifetime data analysis. In the semiparametric method outlined here, one can, as a by-product, infer the number of failed components for a censored system lifetime when it is unobserved. The method of data augmentation can be used when the sufficient statistic is not order dependent—otherwise one can always use the original likelihood and use one of the nonconjugate sampling methods outlined in Neal [38]. This discussion is not exhaustive but is intended to give a flavor of the current state of the art. Owing to advances in computing, realistic models, which were once avoided because of difficulty in implementation, will be becoming more popular.

Degradation Models

Introduction

Reliability testing typically generates product lifetime data, but for some tests, **covariate** information about the wear and tear on the product during the **life test** can provide additional insight into the product's lifetime distribution. This usage, or **degradation**, can be the physical parameters of the product (e.g., corrosion thickness on a metal plate) or merely indicated through product performance (e.g., the luminosity of a light emitting diode). The measurements made across the product's lifetime are *degradation data*, and *degradation analysis* is the statistical tool for providing inference about the lifetime distribution from the degradation data.

Degradation testing and analysis is tied in with accelerated life testing (ALT) because both methods have evolved in recent years to suit reliability tests for which product lifetimes are expected to last far beyond the allotted test time (*see Accelerated Life Models*). ALT is meant to expedite product failure during test intervals by stressing the product beyond its normal use. This helps to bring in more information if the link between the accelerated test environment and the regular use environment is known. The same is true of degradation analysis. If the link between the measure of degradation and lifetime is clearly known, the degradation data provide valuable information about product reliability. Accelerated degradation testing (ADT) combines these two approaches by testing products in harsh environments and measuring the evidence of product degradation during the ALT.

Degradation analysis is especially useful for tests in which soft failures occur; that is, the lifetime of the test item is said to end after the measured performance decreases to a predetermined threshold value that designates a nonfunctioning state or an incipient failure. For a test of material strength, as an example, the degradation measurement might be the increasing size of the largest observed crack in the material, or the amount of corrosion measured on the surface. A failure event can be designated long before the material actually breaks. As another example, electronic components function reliably if their resistance, capacitance and voltage stay within

design limits, and failure can be said to occur when one or more of these parameters degrades beyond a specified limit. Ohring [1] presents a comprehensive array of physical models for electronic devices. Similarly, light emitting devices may be considered to fail only after the luminosity degrades below a fixed measured limit.

Figures 1 and 2 illustrate two different examples of degradation data. Figure 1, from Bogdanoff and Kozin [2] and featured in Meeker and Escobar [3], shows the measured crack size for alloy specimens that were fatigued by rapid cycling. Twelve of the 21 test items failed because their crack sizes exceeded the fixed threshold of 1.6 inches. Nine other test items did not fail, and if the degradation model is sound, more information will be gained from the degradation measurements in these nine observations compared to the respective lifetime measurements, which are right censored.

Figure 2 shows the measured degradation path for light emission of seven vacuum fluorescent displays (VFDs). The VFDs were tested for 200 h in an accelerated failure environment, so this is an example of an ADT. See Bae and Kvam [4] for details. In this case, the degradation path of each test item reaches the failure threshold (defined as the time the luminosity decreases by 50%) where a soft failure is defined.

Degradation Modeling

Models for degradation are generally either data-driven or derived from physical principles via stochastic processes. Although the data-driven model is more commonly applied to analyze degradation data, viewing degradation through stochastic processes helps researchers theoretically characterize the failure process.

Data-Driven Model

The measured degradation path for the i th tested device ($i = 1, \dots, n$) will consist of a vector of m_i measurements made at time points $t_{i1}, \dots, t_{im_i}$. The VFDs in Figure 2, for example, were each measured at the same five time points (0, 24, 72, 100, and 200 h). The measured degradation at t can be modeled as the actual unknown degradation $\eta(t)$

2 Degradation Models

Figure 1 Alloy fatigue crack size (in inches), observations, measured in millions of cycles

Figure 2 Luminosity degradation in seven VFD devices

plus a measurement error term ϵ . At the m_i time points, the degradation measurements of device i are

$$y_{ij} = \eta(t_{ij}) + \epsilon_{ij}, \quad 1 \leq i \leq n, \quad 1 \leq j \leq m_i \quad (1)$$

The form of η can be chosen to have a strict form or it can be more arbitrary. For example, the degradation of many electronic components is known to be of a log-linear form. That is, if we replace y with $\log(y)$, η can be a linear function of time such as $\eta(t) = \beta_1 + \beta_2 t$. On the other hand, the form for degradation can be unknown and nonparametric regression techniques are required to analyze the degradation data. Shiau and Lin [5] use this approach, but compared to a well chosen parametric model, their method can be quite inefficient. However, they show that the nonparametric technique can be useful for selecting a suitable parametric form of η .

If a specific form is described for η , we will have an unknown set of parameter values $\beta = (\beta_1, \dots, \beta_k)$ that must be estimated in order to fully characterize the degradation. In any realistic application of degradation analysis, the test units will degrade in a similar way but on distinct paths. To model this *unit-to-unit variability*, a distribution is assigned to β , allowing n distinctive paths to describe the degradation of the n test units. Meeker and Escobar [3] present a convincing argument for why the **normal distribution** adequately characterizes this randomness (i.e., $\beta \sim \mathcal{N}(\bar{\beta}, \Sigma)$). Along with β , let λ represent unknown parameters that are common across test units (thus no random effects are necessary) so the degradation path is expressed by

$$y_{ij} = \eta(t_{ij}; \lambda, \beta_i) + \epsilon_{ij}, \quad 1 \leq i \leq n, \quad 1 \leq j \leq m_i \quad (2)$$

Degradation Processes

In many experiments, degradation is a continuous progression of wear and decay, so it makes intuitive sense to model the degradation path with a stochastic process. If we let a stochastic process $W(t)$ to describe the degradation level of an item at time t , the mean degradation $\mu(t) = E[W(t)]$ is typically increasing and sometimes known through physical principles. For example, the wear on an automobile tire might be measured in terms of usage (t = odometer reading) and if the tire wear is constant, $\mu(t) = \lambda t$ for some unknown value λ .

The degradation characteristics of several electronic components can be described through stochastic processes. For example, Mitsuo [6] determined the mean degradation for light emitting diodes as $\mu(t) = \lambda t^k$ for some $\lambda > 0$ and $k \in \mathbb{R}$. Aven and Jensen [7] show how different processes imply different lifetime distributions. For example, in the case where the degradation follows a Wiener process, the time when the degradation level first reaches a fixed failure threshold has an inverse Gaussian distribution.

Stochastic processes are also helpful to infer lifetime distributions from **damage models**, which are a special case of degradation models, for example, see Kahle and Wendt [8]. For example, suppose $M(t)$ is a Poisson shock process with rate λ . Let P_k be the probability that the system survives k shocks, so that $1 = P_0 \leq P_1 \leq P_2 \leq \dots$. Then, the system survival can be expressed as

$$\sum_{k=0}^{\infty} P_k \frac{(\lambda t)^k}{k!} e^{-\lambda t}$$

If $P_{i+j} \leq P_i P_j$, then compared to a new device, the probability of surviving k additional shocks is smaller when the device has already absorbed some shocks. Based on this premise, it is possible to show that the lifetime distribution is *new better than used*, that is, for any $x, y > 0$, $P(X \geq x)P(X \geq y) \geq P(X \geq x + y)$ (see **Stochastic Orders and Aging**).

Relating Degradation to Lifetime

If the **physics of failure** is known through the model of an item's degradation over time, it's lifetime distribution can be inferred from this model as well (see **Degradation and Failure**). For materials, specimens exposed to constant stress cycles in a given stress range, lifetime is measured in number-of-cycles until failure (N). The Whöler curve (or $S - N$ curve) relates stress level (S) to N as $NS^b = k$, with known material parameters b and k . The $S - N$ equation is expressed in log form as $Y = \log N = \log k - b \log S$. If N is log-normally distributed, Y is normally distributed and regular regression models can be applied for predicting cycles-to-failure. The log-normal distribution is considered for modeling the failure time distribution when the corresponding degradation process based on rates that combine multiplicatively, and it is convenient for modeling fatigue

4 Degradation Models

crack growth in metals and composites. Sobczyk and Spencer [9] features numerous settings and examples.

An alternative model based on fatigue, introduced by Birnbaum and Saunders [10], defined B_n to be the measurable damage (*see Cumulative Damage Models Based on Gamma Processes*) to the test item after n cycles with accumulated amount of damage ζ_i in the i th cycle via $B_n = \zeta_1 + \dots + \zeta_n$, $i = 1, \dots, n$. If the ζ_i s are identically and independently distributed as with mean μ and variance σ^2 ,

$$P(N \leq n) = P(B_n > B^*) \approx \Phi\left(\frac{B^* - n\mu}{\sigma\sqrt{n}}\right) \quad (3)$$

where Φ is the standard normal cumulative distribution function (CDF). This results because B_n will be approximately normal if n is large enough. The reliability function for the test unit is

$$R(t) \approx \Phi\left(\frac{B^* - n\mu}{\sigma\sqrt{n}}\right) \quad (4)$$

This is called the *Birnbaum–Saunders* distribution, and it follows that

$$W = \frac{\mu\sqrt{N}}{\sigma} - \frac{B^*}{\sigma\sqrt{N}} \quad (5)$$

has a normal distribution, which leads to accessible implementation in lifetime modeling. Bogdanoff and Kozin [2] overview properties of the Birnbaum–Saunders distribution for materials testing.

Statistical Inference

If we assume the degradation path model in equation (2), with item-to-item variability reflected through random coefficients in η , we have an accumulated set of unknown parameters $\theta = (\lambda, \bar{\beta}, \Sigma)$, which makes for a difficult computation of the lifetime distribution. Numerical methods and simulations are typically employed to generate point estimates and confidence statements.

In selecting a degradation model based on longitudinal measurements of degradation, monotonic models are typically chosen under the assumption that degradation is a one-way process. From the degradation model, the lifetime distribution is defined as the

time at which the degradation first reaches the failure threshold, designated y^* :

$$F(t) = P(y(t) > y^*) = P(\eta(t; \lambda, \beta) + \epsilon > y^*) \quad (6)$$

Least squares (**Least-Squares Estimation**) or maximum likelihood (**Maximum Likelihood**) can be used to estimate the unknown parameters in the degradation model. To estimate $F(t_0)$, one can simulate N degradation curves from the estimated regression by generating N random coefficients $\theta_1, \dots, \theta_N$ from the estimated distribution $G(\theta; \hat{\beta})$. Next compute the estimated degradation curve for y_i based on the model with θ_i and $\hat{\lambda}$: $y_i(t) = \eta_i(t; \hat{\lambda}, \theta_i)$. Then $\hat{F}(t_0)$ is the proportion of the N generated curves that have reached the failure threshold y^* by time t_0 .

A nonparametric **bootstrap** sampling procedure can be used for measuring the uncertainty in the lifetime distribution estimate. The bootstrap procedure *resamples* the sample degradation curves *with replacement* (i.e., so some curves may not be represented in the sample while others may be represented multiple times). Meeker and Escobar [3] summarize a bootstrap procedure for making **confidence intervals** for the lifetime distribution:

1. Compute estimates of parameters $\bar{\beta}$, λ , Σ .
2. Use simulation (above) to construct $\hat{F}(t_0)$.
3. Generate $N \geq 1000$ bootstrap samples, and for each one, compute estimates $\hat{F}^{(1)}(t_0), \dots, \hat{F}^{(N)}(t_0)$. This is done as before except now the M simulated degradation paths are constructed with an error term generated from $H(\eta; \hat{\Sigma})$ to reflect variability in any single degradation path.
4. With the collection of bootstrap estimates in equation (7), compute a $1 - \alpha$ level confidence interval for $F(t_0)$ as $(\hat{F}^l(t_0), \hat{F}^u(t_0))$, where the indexes $1 \leq l \leq u \leq N$ are calculated as $N^{-1} = \Phi(2\Phi^{-0.5}(p_0) + \Phi^{-0.5}(0.5\alpha))$ and $uN^{-1} = \Phi(2\Phi^{-0.5}(p_0) + \Phi^{-0.5}(0.5(1 - \alpha)))$, and p_0 is the proportion of bootstrap estimates of $F(t_0)$ less than $\hat{F}(t_0)$.

Example

The VFDs are tested (see Figure 2) at higher filament voltage level than normal usage condition

(Ef = 4.55 V). It is known that the display luminosity for VFDs decreases exponentially over most of the usage period when the degradation path can be expressed as

$$\Lambda(t) = \beta_0 \exp(-\beta_1 t) \quad (7)$$

where $\Lambda(t)$ denotes the luminosity at time t , β_0 is the initial luminosity, and β_1 is the rate of degradation. The light device is considered to fail at the time its luminosity decreases below 50% of its initial measurement. That is, failure is defined as the first time relative luminosity

$$y(t) = \frac{\Lambda(t)}{\Lambda(0)} = \exp(-\beta_1 t) \quad (8)$$

falls below 0.5. Using least-squares regression with the log transformation $\log y(t) = -\beta_1 t$, and by ignoring variation between individuals, the fitted (no-intercept) model is

$$\log y(t) = -0.0048t \quad (9)$$

with $R^2 = 0.9893$. However, the model fails to reflect individual variation of degradation rate (see Table 1).

To reflect individual variation of degradation, a linear random-coefficients model can be applied by assuming that β_1 is random. The random effects model can be written as

$$\log y(t_{ij}) = -(\beta + u_i)t_{ij} + \epsilon_{ij} \quad (10)$$

where t_{ij} is the covariate for the j th measurement time on the i th individual, $\epsilon_{ij} \sim \mathcal{N}(0, \sigma^2)$, and $u_i \sim \mathcal{N}(0, \sigma_u^2)$. Using the SAS NLMIXED procedure, the fitted linear random-coefficients model is computed numerically as

$$\log y(t_{ij}) = -0.004751t_{ij} \quad (11)$$

Table 1 Estimated degradation rates for VFDs in Figure 2

Sample	Degradation rate
1	4.6×10^{-3}
2	5.1×10^{-3}
3	4.6×10^{-3}
4	5.1×10^{-3}
5	4.8×10^{-3}
6	4.0×10^{-3}
7	5.0×10^{-3}

with $\hat{\sigma}_u^2 = 0.001574$ and $\hat{\sigma}^2 = 1.032 \times 10^{-7}$. Based on the estimated parameters, the fitted lines are given in Figure 3.

Comments

Degradation measurements have great potential to improve lifetime data analysis, but they also introduce new problems to the statistical inference. Lifetime models have been researched and refined for many manufactured products that are put on test. On the other hand, parametric degradation models tend to be based on simple physical properties of the test item and its environment (e.g., the Paris crack law, Arrhenius rule, Power law) which often lead to obscure lifetime models. Meeker and Escobar [3] show that most valid degradation models will not yield lifetime distributions with closed-form solutions. Given the improving computational tools available to researchers, this should be no deterrent to using degradation analysis.

In a setting where the lifetime distribution is known, but the degradation distribution is unknown, degradation information does not necessarily complement the available lifetime data. For example, the lifetime data may be distributed as Weibull, but conventional degradation models will contradict the Weibull assumption (actually, the rarely used *reciprocal Weibull* distribution for degradation with a fixed failure threshold leads to Weibull lifetimes). Bae *et al.* [11] discuss this problem in terms of a simple additive degradation model.

Finally, the monotone relationship between degradation and usage (or time) does not necessarily hold for all applications. Bae and Kvam [12] analyze light display data for a VFD that shows nonmonotonic degradation during its **burn-in** period (*see Burn-In and Maintenance Policies*), when impurities in the vacuum are being burned off. As this happens, luminosity actually increases slightly before beginning a long and steady decrease over its usage period. In this case, a more complicated mixture model that captures the burn-in effect proves to be more efficient.

Compared to ordinary life testing or even ALT, degradation analysis procedures tend to be computationally cumbersome. However, for important applications, the increase in statistical efficiency can be dramatic. In the past, these computations have

Figure 3 Fitted degradation model

impeded degradation analysis from being a feature of reliability problem solving. Such analyses are easier to implement now, and the reliability analyst need not be coerced into using an overly simplistic model – for instance, a linear model that does not allow for random coefficients. Chen and Zheng [13] construct an **imputation** algorithm to generate a closed-form solution, although its performance is suspect for medium or small samples.

Robinson and Crowder [14] introduce a Bayesian approach and showed if **prior distributions** are chosen from a reasonable class, they have negligible effect on the lifetime **estimation**. Bayesian reliability is summarized in **Bayesian Reliability Analysis**. In most cases the Bayesian procedure is even more computational than the one introduced here, but **Markov chain Monte Carlo** (e.g., **Hierarchical Markov Chain Monte Carlo (MCMC)** for

Bayesian System Reliability) methods have straightforward implementation.

Reliability Growth Modeling

Introduction

Modeling reliability growth (RG) has received considerable attention in the statistical and engineering literature over the past four decades. At the initial developmental phase of any production involving complex systems, a test-analyze-and-fix (TAAF) process is often undertaken to promote the detection of system faults and incorporate appropriate redesigns or other corrective actions, and the modified system is retested. As this test–redesign–retest sequence contributes to an improvement in the system performance, failure data become increasingly sparse at the later stages of testing making it more difficult to assess the current reliability. An RG model provides a structure through which the failure data from the current as well as previous stages of testing could be analyzed in an integrated way to make efficient inference on system reliability, and other aspects of the underlying failure process.

RG models have been applied extensively in analyzing failure data arising from hardware as well as a piece of software. Further, for systems with single-shot missions that undergo a developmental program, RG models arise quite naturally while studying the effectiveness of design fixes. Below we describe some popular RG models that have been developed in the context of observing either time-to-failure or a sequence of dichotomous/trichotomous outcomes.

Continuous-Time RG Models

The continuous-time RG models are typically classified into two general categories; one class models the *time between successive failures*, whereas the other category builds on a modeling framework directly applied to the cumulative count of failures viewed over the continuum of time. Following Singpurwalla and Wilson [1] we shall term these two classes *Type-I* and *Type-II models*, respectively, noting that a model of each type generates a unique model of the other type. In the discussion that follows, we shall describe some

of the more commonly used models under each classification.

A major thrust to RG modeling in the area of hardware reliability rose from certain empirical findings in Duane [2] from examination of the failure data of a variety of systems such as complex hydromechanical devices, aircraft generators, and jet engines in the course of their development. When plotted on a log–log scale, the cumulative number of failures was typically found to produce a linear pattern of relationship with the cumulative operating time. This phenomenon, later came to be known as the *Duane postulate*, was given a concrete stochastic basis in Crow [3], where failures during the development stage of a new system were assumed to follow a nonhomogeneous **Poisson process** (NHPP) with an **intensity function** $\lambda(t)$ of the Weibull form

$$\lambda(t) = \mu \delta t^{\delta-1} \quad (1)$$

Note that equation (1) corresponds to a Type-II model according to the classification scheme described above. The case $\delta < 1$, corresponds to a decrease in the failure intensity and hence, a growth in reliability. The corresponding cumulative failure rate μt^δ is linear with the accumulated time on a log–log scale. Incidentally, an NHPP formulation was originally proposed by Ascher [4] in modeling the reliability change of a *bad-as-old system*, and was later used by Bassin [5] with the Weibull intensity to obtain optimal overhaul intervals for various machines. A large body of literature has evolved thereafter, focusing on theoretical developments as well as applications of equation (1) in RG analysis. Under this model, a thorough treatment of maximum-likelihood **estimation** and confidence procedures for the parameters was provided by Crow [3] under both time-truncated and failure-truncated testing schemes applied to one or more systems. Testing procedures for equality of the scale parameters for two or more independent systems were studied by Lee [6] under the time-truncated scheme. Exact **confidence intervals** for the scale parameter under the failure-truncated scheme were obtained by Finkelstein [7] using **Monte Carlo** methods. Sequential testing procedures for the growth parameter δ was discussed by Bain and Engelhardt [8]. Inferences on the current system reliability were studied by Lee and Lee [9], Bain and Engelhardt [10], Crow [11], Rigdon and Basu [12], and Sen and Khattree [13].

2 Reliability Growth Modeling

In the continuous-time case, the NHPP with Weibull intensity has gained vast popularity due to its empirical fit to a variety of data *vis-a-vis* its conformity to the Duane learning curve, and availability of elegant distributional results concerning statistical inferences. While empirical fit, nice mathematical properties, and tractability of statistical inferences are important aspects of a stochastic model, a clear physical interpretation is also of paramount importance. Finkelstein [14] pointed out that the Weibull intensity $\lambda(t)$ has the rather unrealistic feature that it tends to ∞ as $t \rightarrow 0$ and to 0 as $t \rightarrow \infty$. Finkelstein and later Littlewood [15] discussed some modifications of the NHPP model to overcome these difficulties. Aside from these limiting values, there is an even more serious criticism concerning the principle of this modeling. Duane [2] indicated that a learning curve is used to monitor developmental progress and plan for reliability improvement. The major point of concern with the NHPP model is its continually changing intensity function irrespective of the failure history, which is in direct conflict with the concept of the Duane learning curve, as well as the conceptual framework of a test–redesign–retest course of development program. If system improvement is assumed to be effected only after a failure is observed, a realistic model should be flexible enough to incorporate a change in the failure rate at the occurrences of the failures. Thompson [16] expressed the same concern by saying that “... some provision needs to be present for altering the process of failures when modifications or corrective actions are applied to the system”.

Incorporating a step change in the failure pattern at the occurrences of successive failures, Sen and Bhattacharyya [17] proposed a Type-I RG model, in which the successive interfailure times are distributed as independent exponential random variables with hazard λ_i at the i th stage of the process. The authors investigated the specific RG parameterization

$$\lambda_i = (\mu/\delta)i^{1-\delta}, \quad \mu > 0, \quad \delta \geq 1 \quad (2)$$

that is intimately connected to the Duane learning curve property described above. The authors showed that under the sampling scheme of observing a pre-specified number of failures, the maximum-likelihood estimators (MLEs) of the parameters are jointly asymptotically *singular* normal with quite nonstandard rates of convergence. More recently, Sen [18] investigated exact as well as large-sample inference

of the estimate of the current intensity, as evaluated at the end of the testing stage.

In the area of software engineering, reliability is viewed synonymously with the probability of failure-free operation of a software code in a prespecified duration. In contrast to the field of hardware reliability, a distinctively large number of RG models have been proposed that have applications in error detection in software programs. One of the earliest, and perhaps the most well-studied software RG model is a Type-I model proposed by Jelinski and Moranda [19], in which the time between the $(i-1)$ st and the i th failure of the software is distributed as an exponential random variable with hazard

$$\lambda_i = \Lambda(N - i + 1), \quad \Lambda > 0, \quad N \text{ integer} \quad (3)$$

independently of other interfailure times. In this parameterization, N denotes an unknown fixed number of bugs present in the code, and Λ is a constant of proportionality. While the importance of the model in equation (3) is immense in terms of initialing the formalization of software RG models, some aspects of the model have drawn criticisms from researchers in this area. Specifically, the assumptions underlying the formulation of equation (3) of (a) equal contribution from each bug to the failure rate and (b) a perfect repair mechanism, are often thought to be overly simplistic, and not true descriptions of the failure process. In view of countering criticism (a), Moranda [20] modified the hazard rate to be of the geometric decay form

$$\lambda_i = D\rho^{i-1}, \quad D > 0, \quad 0 < \rho < 1 \quad (4)$$

Goel and Okumoto [21] imposed the possibility of **imperfect repair** directly within the modeling framework of equation (3) by rewriting the hazard rate as

$$\lambda_i = \Lambda(N - p(i-1)), \quad \Lambda > 0, \quad N \text{ integer}, \quad 0 < p < 1 \quad (5)$$

where p is the probability that a bug is detected and repaired. Schick and Wolverton [22] generalized equation (3) in a direction distinct from the rest by assuming that the conditional failure rate of the i th event is proportional to the number of remaining bugs as well as the accumulated time since last failure. This is tantamount to assuming yet another Type-I model

with an increasing linear rate of failure (starting at zero at each failure), governing the successive interfailure times. The underlying rationale for such a model reflects the belief that a software is highly reliable after a repair, and the reliability decays with time until the next failure (and bug removal) occurs.

A variant of the usual Type-I RG model that directly models the interdependence between the times between failures has been considered by Singpurwalla and Soyer [23]. Specifically, they assume the interfailure times T_i , $i = 1, 2, \dots$ to satisfy the autoregressive relationship

$$\log T_i = \theta_i \log T_{i-1} + \epsilon_i \quad (6)$$

In equation (6) if T_i 's are scaled to have values larger than 1, values of θ_i greater than 1 would imply RG. Under the assumption of normality of $\log T_i$'s and ϵ_i 's, Singpurwalla and Soyer [23] treat θ_i as random effects and offer Bayesian solution to the inference problem associated with equation (6).

Several Type-II models in the context of modeling growth in software reliability have been proposed in the literature. One of the earliest of them is the model proposed by Goel and Okumoto [24], which assumes the counting process of failures to follow an NHPP with intensity function

$$\lambda(t) = ab \exp(-bt), \quad a > 0, b > 0 \quad (7)$$

In equation (7), a symbolizes the average number of failures to be found "eventually", and b is the growth rate in reliability. Musa and Okumoto [25] postulate a relationship

$$\lambda(t) = \lambda \exp(-\theta M(t)), \quad \lambda > 0, \theta > 0 \quad (8)$$

between the intensity function $\lambda(t)$ and the mean number of failures $M(t)$ up to time t of an NHPP. Both equations (7) and (8) entertain the possibility of having an infinite number of bugs in the software with the interfailure times being stochastically dependent, two features that distinguish them from the usual Type-I models. Additionally, the parameterization in equation (7) imposes a positive probability at infinity for the random variable denoting time to first failure. This may be a realistic assumption for a software code that is a newer release (version) of an older software which has undergone several iterations of development.

A number of Bayesian formulations of both types of models described above have been proposed

in the literature. The Bayesian estimation problem for equation (1) has specifically been addressed by Higgins and Tsokos [26], Guida *et al.* [27], Barlev *et al.* [28], and Sen [29]. A general Bayesian framework for the class of NHPP models has been put forth by Kuo and Lang [30].

In the context of Bayesian inference within the class of Type-I models, substantial effort has been invested in studying *piecewise exponential* models, i.e. models with independent and exponentially distributed interfailure times, where the means λ_i are explicit functions of cumulative failure numbers. Various parametric forms for λ_i have been studied in a Bayesian context by several authors (e.g., Littlewood and Verrall [31], Mazzuchi and Soyer [32], and Soyer [33]). In a more recent work, Erkanli *et al.* [34] avoided any parameterization of λ_i 's, and modeled them directly under an *a priori* monotonicity constraint consistent with RG. Basu and Ebrahimi [35] relaxed the monotonicity assumption and modeled the sequence of λ_i 's as a martingale process. Both of these later works relied heavily on the modern computational advances of **Markov chain Monte Carlo** procedures.

Discrete-Time RG Models

For single-mission systems, the test results are binary in nature as opposed to time to failure in a continuous-time framework. Growth in reliability in the discrete case is demonstrated by an increment in the probability of success at successive stages of the development program. The genesis of the discrete RG models has its roots in the early attempt to quantify the increase in system reliability attained after implementing posttest design changes. Numerous proposals for rescoring "observed failures" as "adjusted partial successes" have been put forth in the literature. Simulations showed, however, that most of the proposed methods were very sensitive to the choice of the failure-discounting parameter(s), which was somewhat arbitrary.

A more formal approach is undertaken by considering that the developmental phase comprises a sequence of independent Bernoulli trials that are not identically distributed across stages. Let p_i denote the probability of success at the i th stage of a developmental program. On the basis of the data of x_i successes in n_i trials at stage i , $i = 1, \dots, n$, Barlow *et al.* [36] obtained MLEs for p_i 's under the

order restriction $p_1 \leq \dots \leq p_n$. An extension of the dichotomous characterization of the trial outcome to the case of partitioning of failures in two distinct categories, namely, assignable-cause and inherent, has been an area of major research interest to the reliability practitioners for a long time. The former corresponds to failure modes that can be eliminated by redesigns or by equipment or operational modifications, while the latter reflects the state of the art and remains unchanged as the system configuration advances. Wolman [37] initialized work in this area, although his study was confined to the calculation of probabilistic quantities, such as “chance of eliminating all assignable-cause failure modes by trial n ”. Barlow and Scheuer [38] followed up with a formal trinomial formulation of the process. They assumed that the probability of an inherent failure q_0 remains a constant throughout the developmental program, while the RG feature manifests itself into a decrease of q_i , the probability of the assignable-cause failure, over successive stages. They obtained MLEs for q_0 and for the q_i ’s subject to the monotonicity constraint $q_i < q_{i-1}$.

On the basis of an extensive simulation study, Olsen [39] investigated the pros and cons of the Barlow–Scheuer restricted MLEs. It is concluded in [39] that these estimators should only be used when (a) a reasonably large sample size is available after the last set of corrections, (b) testing is stopped with the occurrence of assignable-cause failures, (c) corrective actions do not fully remove individual failure modes or introduce new failure modes. It was noted that, in general, the Barlow–Scheuer methodology yielded positive biased estimator $\hat{R}_n = 1 - \hat{q}_0 - \hat{q}_n$ for reliability R_n at the n th (final) stage of testing.

Weinrich and Gross [40] and Mazzuchi and Soyer [41] investigated Bayesian formulations of the Barlow–Scheuer piecewise trinomial model. The modification of the Barlow–Scheuer model in [40] entails redistribution of the probability among other causes of inherent and assignable-cause failure, upon removal of an assignable-cause failure mode. Assuming the initial probabilities (success, assignable cause, inherent cause) to possess a Dirichlet **pdf**, the posterior *pdf* of stage- k probabilities is updated as either a Dirichlet or a mixture of Dirichlet depending on the extent of knowledge of the amount of initial assignable-cause failures removed. Instead of specifying a prior for the probabilities only at the initial

stage, Mazzuchi and Soyer [41] imposed a Dirichlet prior on the differences of the assignable-cause probabilities from successive stages. This clever manipulation clearly defines a *pdf* for the assignable-cause probabilities decreasing across stages. The major contributions of Mazzuchi and Soyer [41] formulations were (a) specification of the prior belief in the entire RG pattern, (b) retention of all relevant marginal and posterior *pdf*’s as tractable Dirichlet (or β) forms, and (c) flexible framework for elicitation of prior information from experts.

Under the construct of observing single-shot trials with dichotomous outcomes, a large class of RG models that adheres to a specific parametric form for the probability of success (reliability) p_k at the k th stage of the developmental process has been investigated over the years. Some of the earlier models of this type were extensively studied by Lloyd and Lipow [42] and Gross and Kamins [43, 44]. The “Gompertz” model proposed in Virene [45] is an interesting inclusion in this class in the sense that it was the only model of this form which attempted to characterize S-shaped patterns for RG.

Recent research in discrete reliability models has devoted considerable attention to another class of parametric models intimately linked to the Duane learning curve property described in the previous section. Identifying a single trial to a unit time in the continuous case, Crow [46] developed the following model used extensively by the US Army:

$$p_k = 1 - \lambda \left[(N_k)^\beta - (N_{k-1})^\beta \right] / n_k, \\ 0 < \lambda < 1, \quad 0 < \beta < 1 \quad (9)$$

where k denotes the configuration number, N_k denotes the cumulative number of test trials until the k th configuration, $N_0 \equiv 0$, and $n_k = N_k - N_{k-1}$. The derivation rested on the underlying assumption that for each stage of testing, the number of observations is fixed and the distribution of outcomes in successes and failures is random. Such a situation can arise, for example, when the system producer delivers batches for sequential phases of testing, all of the scheduled test events are executed, and the results for each stage lead to modifications of the system design. Some estimation procedures for this model were suggested by Crow [46] and Finkelstein [47]; asymptotic properties were studied by Bhattacharyya *et al.* [48], Bhattacharyya and Ghosh [49], and Johnson [50].

The development of the models described above is incompatible with another common strategy of stopping testing as soon as any failure occurs and introducing system redesigns or corrective actions as soon as possible, i.e. inverse sampling. This, in particular, is a viable model for destructive testing of very expensive systems, e.g. testing of the launch and landing capabilities of unmanned aerial vehicles. One of the earlier models under this framework was proposed by Dubman and Sherman [51], who considered the formulation

$$p_k = 1 - q\rho^k \quad (10)$$

which amounts to a “geometric decay” in the unreliability. The focus of the detailed study by Dubman and Sherman [51] was on the asymptotic properties of the MLEs. Fries [52] took the learning curve property and directly imposed the inverse sampling strategy to derive the following model expressed as

$$p_k = 1 - \lambda' \left[k^{\beta'} - (k-1)^{\beta'} \right]^{-1}, 0 < \lambda' < 1, \beta' > 1 \quad (11)$$

The inference procedures for equation (11) as well as the effects of using results from the direct-sampling model (9) to data which is generated from equation (11) have been documented in Sen and Fries [53, 54].

Concluding Remarks

RG modeling is often deemed to fall under the larger area of studying **repairable systems**. While some of the models described above can be easily extended to incorporate *decay* in reliability, thereby making it a candidate for modeling failures of a repairable system, others are quite specifically designed to depict a growth in reliability. It is important to realize that the major focus in RG modeling is an assessment of system improvement effected by the design changes. Further, the models described above are mostly appropriate for analyzing a modest chain of events from a single system. The context is relevant for studying very complex, expensive systems, for which only one or a very small number of prototypes may be available. When only a few failures are observed for a substantially large number of systems/units, such as in many medical and manufacturing applications, a nonparametric or semiparametric approach is deemed more reasonable. Substantial

methodological advances have been made in this area, which clearly is focused on issues far removed from the topic of RG modeling, and hence, is not covered in this article.

Multicomponent Maintenance

Introduction

Multicomponent maintenance is the problem of finding optimal **maintenance policies** for a system consisting of several units of machines or many pieces of equipment, which may or may not depend on each other [1]. Owing to the existence of interactions between components in complex systems, applying single-component maintenance policies is often not optimal. Generally, three types of interactions or dependencies can be distinguished: economic dependence, stochastic dependence, and structural dependence. Economic dependence implies that grouping maintenance actions either saves costs (e.g. because to economies of scale) or yields higher costs (e.g. because of machine downtime) compared to multiple individual maintenance actions. Stochastic dependence occurs if the condition of components influences the lifetime distribution of other components. Structural dependence applies if components structurally form a part, so that the maintenance of a failed component implies maintenance of working components. Before we discuss these dependencies in more detail, we will first give a historical perspective on multicomponent maintenance.

Historical Perspective

Multicomponent maintenance is one of the key problems in maintenance management of complex systems. Intense scientific interest in problems related to maintenance management originated only a few decades ago. The basis for the scientific support of maintenance is found in reliability engineering. The book *Mathematical Theory of Reliability* [2] indicates the start of scientific interest in maintenance problems. In the early stages, maintenance was almost exclusively interpreted as replacement of components (see **Replacement Strategies**). The development of some simple but insightful models describing aging phenomena of technical components, as well as the choice of appropriate actions to cope with these phenomena, showed that a scientific approach can be

useful. In the 1970s and early 1980s, the basic models were extended in several directions. A substantial part of this work was primarily motivated by mathematical curiosity, rather than practical need.

In the 1980s, scientists made a step forward in bridging the gap between analytical models and practice by a systematic analysis of multicomponent systems. Multicomponent systems are much closer to reality than the classical single-component systems. Since maintenance actions in practice quite often come down to the replacement of one or more components in a multicomponent system, the study of these systems was an adequate way to bring reliability studies closer to practical maintenance management. Moreover, similar to many other areas of applied (stochastic) optimization (see **Reliability of Redundant Systems**), the major advances in information technology brought the use of quantitative analytic models within computational reach.

During the last 15 years substantial progress has been made in developing quantitative decision support systems for maintenance management of complex systems. Sophisticated decision support systems are in operation nowadays in the oil industry (both for maintenance of refineries as well as offshore installations), road and railways maintenance, and electric power generation. The number of companies that make use of some kind of quantitative tools to support inspection and replacement of equipment is increasing rapidly.

Dependencies in Multicomponent Systems

Thomas [3] defines three different types of interactions between components: economic, stochastic, and structural. Below, we will discuss these dependencies in more detail.

Economic Dependence

In simple terms, economic dependence implies that the cost of joint maintenance of a group of components does not equal the total cost of individual maintenance of these components. The effect of this dependence comes to the fore in the execution of maintenance activities. The joint execution of maintenance activities can save costs in some cases, but can lead to higher costs in other cases or it may not be allowed. So, we can further subdivide the models

2 Multicomponent Maintenance

with economic dependence into positive and negative economic dependence. In many multicomponent systems both forms of economic dependence between components exist. As an example, we will discuss the different dependencies in *k-out-of-n* systems.

Positive Economic Dependence. We distinguish between the following forms of positive dependence:

- economies of scale
 - general
 - single setup
 - multiple setups
 - hierarchy of setups
- downtime opportunity.

The term *economies of scale* is often used to indicate that joint maintenance activities are cheaper than multiple individual activities. Economies of scale can result from preparatory or setup activities that can be shared when several components are maintained simultaneously. The cost of this setup work is often called *setup cost*. Setup costs can be saved because the execution of a group of activities requires only one setup. In practice, maintenance of multicomponent systems requires different setup activities and in that case there usually is a hierarchy of setups. For instance, consider a system consisting of two components, which both consist of two subcomponents. Maintenance of the subcomponents of the components may require a setup at system level and component level. Firstly, this means that the setup cost at component level is paid only once when the maintenance of two subcomponents of a component is combined. Secondly, the setup cost at system level is paid only once when all subcomponents are maintained at the same time. In multicomponent maintenance models the setup cost structure is incorporated in the objective function of the corresponding optimization problem.

Another form of positive dependence is the downtime opportunity. Component failures can often be regarded as opportunities for **preventive maintenance** of nonfailed components. In a series system (see **Parallel, Series, and Series-Parallel Systems**) a component failure results in a nonoperating system. In that case it may be worthwhile to replace other components preventively at the same time (opportunistic maintenance). This way the **system downtime** results in savings in maintenance costs

since more components can be replaced at the same time. Moreover, by grouping corrective and preventive maintenance, the downtime can be regulated and in some cases it can even be reduced. In some cases the downtime cost can be included in the setup cost. In general, however, it is difficult to assess the cost associated with the downtime.

Negative Economic Dependence. Negative economic dependence between components occurs when maintaining components simultaneously is more expensive than maintaining components individually. There can be several reasons for this such as:

- manpower restrictions
- safety requirements
- redundancy/production loss.

Firstly, grouping maintenance results in a peak in manpower needs. Manpower restrictions may even be violated and additional labor needs to be hired, which is costly. The problem here is to find the balance between workload fluctuation and grouping maintenance.

Secondly, there are often restrictions on the use of equipment, when executing maintenance activities simultaneously. For instance, use of one equipment may hamper the use of other equipment and cause unsafe operations. Safety requirements often prohibit joint operation.

Thirdly, joint (corrective) maintenance of components in systems in which some kind of redundancy (see **Reliability of Redundant Systems**) is available may not be beneficial. Although there may exist economies of scale through simultaneous repair of a number of (identical) components, leaving components in a failed condition for some time increases the risk of costly production losses. Production loss may increase more than linearly with the number of components out of operation. For an example of this type of economic dependence, we refer to Stengos and Thomas [4].

Economic Dependencies in *k-out-of-n* Systems. The *k-out-of-n* system (see ***k-out-of-n* Systems**) is a typical example of a system with both positive and negative economic dependence between components. A *k-out-of-n* system functions if at least *k* components function. If $k = 1$, then it is a parallel system; if $k = n$, then it is a series system. Let us for

the moment distinguish between the cases $k = n$ and $k < n$.

In the series system ($k = n$, see **Parallel, Series, and Series-Parallel Systems**), positive economic dependence between components is present due to downtime opportunities. The failure of one component results in an expensive downtime of the system and this time can be used to group both preventive and corrective maintenance, i.e. opportunistic grouping. Negative economic dependence is not explicitly present in the series system.

If $k < n$, then there is redundancy in the system and it fails less often than its individual components. In this way a certain reliability can be guaranteed. Typically, the components of this system are identical which allows for economies of scale in the execution of maintenance activities. It is not only possible to obtain savings by grouping preventive maintenance, but also by grouping corrective maintenance. In other words, the redundant components introduce additional positive dependence in the system. Whereas positive economic dependence is present upon failure of a component, negative economic dependence plays a role as long as the system operates. A single failure of a component may not always be an opportunity to combine maintenance activities. Firstly, grouping corrective and preventive maintenance upon the failure of the component increases the probability of system failure and costly production losses. Secondly, leaving components in a failed condition for some time, with the intention to group corrective maintenance at a later stage, has the same effect. So, there is a trade-off between the potential loss resulting from a system failure and the benefit of joint maintenance.

Stochastic Dependence

Stochastic dependence (see **Aging and Positive Dependence**) is also referred to as *failure interaction* and *probabilistic/statistical dependence*. It defines a relationship between components upon failure of a component. For example, it may be the case that the failure of one component induces the failure of other components or causes a shock to other components. Generally, the state of components can influence the state of the other components in the system. Here, the state can be given by the age, the failure rate, state of failure, or another condition measure. In the seminal work on stochastic dependence, Murthy and Nguyen [5, 6] introduce two types of failures: natural

and induced. Natural failures are modeled by random variables and represent “normal” failures because of, e.g. aging or heavy usage. Induced failures are the result of other failures. Typically, there are two ways of modeling the induced failures. Firstly, a (natural) failure of one component induces a failure of other components with probability p and has no effect with probability $1 - p$. Scarf and O’Deara [7, 8] have compared several age- and block-replacement policies (see **Multivariate Age and Multivariate Renewal Replacement; Block Replacement**) for a two-component system with both this type of failure dependence and economic dependence. Secondly, a natural failure of one component may act as a shock to another component, resulting in a higher failure rate or condition of this component. This type of failure interaction is often modeled by a nonhomogeneous Poisson process (see **Poisson Processes**). Özekici [9] proposes a quite general Markov (see **Markov Processes; Maintenance and Markov Decision Models**) model for failure interaction. The state of a component at time t , which is given by a continuous random variable, depends on the state of the system up to time t . The state of the system is again given by the vector of component state values.

Finally, we recognize that the maintenance policies for systems with failure interaction are mainly of an opportunistic nature, since the failure of one component is potentially harmful for other components.

Structural Dependence

Structural dependence (see **Group Maintenance Policies; Total Productive Maintenance**) means that some operating components have to be replaced, or at least dismantled, before failed components can be replaced or repaired. In other words, structural dependence between components indicates that they cannot be maintained independently, but only together. It is not about failure dependence, but about maintenance dependence. Since the failure of a component offers an opportunity to replace other components, opportunistic policies are expected to perform well on systems with structural dependence between components. Obviously, preventive maintenance may also be advantageous, since maintenance of structural dependent components can be grouped.

There may be several reasons for structural dependence. For example, a bicycle chain and a cassette form a union, which should always be replaced

together, rather than individually. Another example is from Dekker *et al.* [10], which considers road maintenance. Several deterioration patterns affect roads, e.g., longitudinal and transversal unevenness, cracking, and raveling. For each mechanism one may define a virtual component, but if one applies a maintenance action to such a component it also affects the state with respect to the other failure mechanisms.

The seminal paper in this category is from Sasieni [11]. He considers the production of rubber tires. The machine that produces the tires consists of two “bladders”; one tire is produced on each bladder simultaneously. Upon failure of a bladder, the machine must be stripped down before replacement can be done. This means that the other bladder can be replaced at the same time. Note that immediate replacement is not mandatory, but a failed bladder will produce faulty tires.

Modeling Multicomponent Maintenance

Several models for the maintenance of multicomponent systems have been proposed. Firstly, these models can be classified based on the planning aspect of the model: stationary (long term) and dynamic (short term). Secondly, one can distinguish three types of optimization methods that can be used to select the model: exact, heuristic, or policy optimization. The typical features of the models in these categories are specified below.

Planning Horizon

In stationary models, a long-term stable situation is assumed and mostly these models assume an infinite planning horizon. This assumption facilitates mathematical analysis. Models of this kind provide static rules for maintenance, which do not change over the planning horizon. They generate for example, long-term maintenance frequencies for groups of related activities or control limits for carrying out maintenance, depending on the state of the components. Three main classes of models in this category can be recognized, namely grouping corrective maintenance, grouping preventive maintenance, and opportunistic maintenance. In the first case, components are only correctively maintained and a failed component can be left in the failed state until its corrective maintenance is carried out jointly with that of other failed

components. In the second case, preventive maintenance is carried out to prevent failures or to decrease operating costs, and this is planned in advance and in such a way that setup costs can be saved by simultaneous execution. In the third case, maintenance is not necessarily planned in advance. However, setup savings can be obtained since (corrective or preventive) maintenance of a component yields an opportunity for maintenance of other components.

In dynamic models, short-term information such as a varying deterioration of components or unexpected opportunities can be taken into account. Situations that are not stationary, such as a varying use of components, and unexpected events that may create an opportunity for doing maintenance at lower costs, can now be incorporated. These models generate dynamic decisions that may change over the planning horizon.

The dynamic-grouping models can be further subdivided into two categories: those with a finite horizon and those with a rolling horizon. Finite-horizon models consider the system in this horizon only, and hence assume implicitly that the system is not used afterward, unless a so-called residual value is incorporated to estimate the industrial value of the system at the end of the horizon. Rolling-horizon models also use a finite horizon, but they do so repeatedly and on the basis of a long-term (infinite-horizon) plan. That is, once decisions of the finite horizon are implemented or when new information becomes available, a new horizon is considered, and a tentative plan based on the long-term one is adapted according to short-term circumstances.

Optimization Method

Exact optimization methods are designed to find the global optimal solution to a problem. However, if the computing time of the optimization method increases exponentially with the number of components, then exact methods are desirable only to a certain extent. In that case, solving problems with many components is impossible and heuristics should be used. Heuristics are local optimization methods that do not pretend to find the global optimum, but can be applied to find a solution to the problem in a reasonable time. The quality of such a solution depends on the problem instance. In some cases, it is possible to give an upper bound on the gap between the optimal solution and the solution found by the heuristic.

In many papers, maintenance planning is done by optimizing a certain type of policy. Well-known maintenance policies are the age- and block-replacement policies (*see Multivariate Age and Multivariate Renewal Replacement; Block Replacement*) and their extensions. The advantage of policy optimization over other optimization methods is that it gives more insight into the solution of the problem. Policy optimization will not always result in the global optimal solution, since there may be another policy that results in a better solution.

Heuristic and exact methods are often used in finite-horizon models, especially when time is discretized and the decision parameters only take integer values. Policy optimization is mainly used in infinite-horizon models. In these models, it is often possible to derive analytical expressions for optimal control parameters and the corresponding optimal costs.

Example

We will now illustrate the preceding review of multicomponent maintenance models with an example. It is based on two studies by Scarf and O'Deara [7, 8], who consider the maintenance of a clutch system in a bus fleet. The system is a series system consisting of the clutch assembly (component 2) and the clutch controller (component 1). In this particular system a (natural) failure of component 1 causes a failure of component 2 with probability 1, whereas a failure of component 2 *never* induces a failure of component 1. Moreover, the system exhibits (positive) economic dependence in that combining (preventive or failure) replacements saves costs. Replacement restores the respective component to a new condition. Below, we highlight two replacement policies for this system: combined failure-based replacement (CFR) and combined age-based replacement (CAR; *see Multivariate Age and Multivariate Renewal Replacement*).

Note that because we deal with a series system (*see Parallel, Series, and Series-Parallel Systems*), a system failure implies that either both components have failed or just one of the components has failed. It is assumed that failed components are replaced immediately. CFR now prescribes that either (a) both failed components are replaced or (b) the failed component is replaced correctively and the component that has not failed is replaced preventively. CAR dictates that

both components are replaced at age T or upon failure, whichever occurs first. Observe that both policies prescribe that components that have not failed are replaced preventively. Scarf and O'Deara [7] also consider age- and failure-based replacement policies that do not replace components that have not failed preventively. Since these policies do not take into account the positive economic dependence between components, they are outperformed by their extensions (CAR and CFR, respectively).

Let us introduce some notation. The cost of a preventive replacement of both components is given by C_{PP} and is less than or equal to the independent preventive replacement of both components. The cost of failure replacement of both components C_{FF} , is assumed to be equal to the cost of combined failure and preventive replacements of the components. The lifetime distribution $F_i(x)$ of component i is the Weibull distribution with parameters α_i and β_i , $i = 1, 2$. That is, $F_i(x) = 1 - \exp(-(x/\beta_i)^{\alpha_i})$, $i = 1, 2$. The lifetime is measured in months. Now, it can be shown that the mean cost rates for CFR and CAR are given by

$$\begin{aligned} C_{\infty}^{\text{CFR}} &= \frac{C_{FF}}{\int_0^{\infty} (1 - F_1(x))(1 - F_2(x)) dx} \quad \text{and} \\ C_{\infty}^{\text{CAR}}(T) &= \frac{C_{FF} + (C_{PP} - C_{FF})(1 - F_1(T))(1 - F_2(T))}{\int_0^T (1 - F_1(x))(1 - F_2(x)) dx} \end{aligned} \quad (1)$$

respectively. Minimizing $C_{\infty}^{\text{CAR}}(T)$ with respect to T yields the optimum replacement age.

Figure 1 shows the (optimal) mean cost rate for CFR and CAR for the lifetime parameters as estimated in [7, 8]. Cost parameter C_{PP} has been set to 2740 and C_{FF} has been varied between 4420 and 6420 (this corresponds with the case studies by Scarf and O'Deara [7], where the unavailability cost is 1600 and the penalty cost of a failure is varied between 0 and 2000). As expected CAR outperforms CFR and the difference becomes more pronounced as the cost of failure increases. Scarf and O'Deara [7] show that the performance (with respect to both mean cost rate and implementation) of CAR is comparable with that of well-performing

Figure 1 Mean cost rate for replacement policies CFR and CAR versus C_{FF} (system failure replacement cost). The Weibull parameters are given by $\alpha_1 = 8$, $\beta_1 = 34.8$, $\alpha_2 = 7.7$, and $\beta_2 = 17.8$. The cost of preventive replacement of both components is $C_{PP} = 2740$. The cost of combined failure and preventive replacements C_{FF} is varied between 4420 and 6420

opportunistic age-replacement policies. Notice that CAR treats the system as a single component and prescribes to replace it at age T . As such it is easy to implement in a decision support system. Moreover, a further study [8] shows that CAR competes with the best (modified) block-replacement policies, which are also relatively easy to manage.

Further Reading

Several overview articles have appeared on multicomponent maintenance models. Cho and Parlar [1] review articles from 1976 up to 1991. It divides the literature into five topical categories: machine-interference/repair models, group/block/cannibalization/opportunistic models, inventory/maintenance models, other maintenance/replacement models, and inspection/maintenance models. Dekker *et al.* [12] exclusively deal with multicomponent maintenance models that are based on economic dependence. The models are classified on the basis of their planning aspect: stationary (long term) or dynamic (short term). Wang [13] gives an overview of maintenance policies of deteriorating systems. The emphasis is on policies for single-component systems. One

section is devoted to opportunistic maintenance policies for multicomponent systems. The author primarily considers models with economic dependence. In a recent article, Nicolai and Dekker [14] review articles in which multicomponent maintenance of systems with economic (both positive and negative), stochastic, and structural dependence is modeled (and optimized).

Markov Renewal Processes in Reliability Modeling

Introduction and Mission Process

In this article, we consider a reliability system that is designed to perform a random sequence of phases or stages with random durations. These are referred to as *phased-mission* or *mission-based systems* where the stochastic structure of the mission process plays a critical role. It is assumed that the mission follows a Markov **renewal process**, and we will analyze various issues related to the reliability of such systems. This line of stochastic modeling and research is often classified under stochastic models in random environments. The idea is used not only in a reliability setting, but in other applications as well. For example, Özekici [1] discusses other applications in inventory and queuing. Asmussen [2] and Rolski *et al.* [3] also give further applications in queuing, insurance, and finance.

In reliability modeling, a device generally consists of a large number of components with stochastically dependent lifetimes. **Random environments** are used to provide a tractable model of dependence since this is taken as an external process that affects the deterioration, aging, and failure of all of the components. Since all components are subjected to the same environmental conditions, their lifetimes are dependent *via* their common environmental process. Thus, the environmental process is actually a factor of variation in the failure structure of the components. An interesting model was introduced by Çınlar and Özekici [4] where stochastic dependence is introduced by a randomly changing common environment that all components of the system are subjected to. This model is based on the simple observation that the aging or deterioration process of any component depends very much on the environment that the component is operating in. They propose to construct an intrinsic clock that ticks differently in different environments to measure the intrinsic age of the device. The environment is modeled by a semi-Markov jump process and the intrinsic age is represented by the cumulative hazard accumulated in time during the operation of the device in the randomly varying

environment. This is a rather stylish choice, which envisions that the intrinsic lifetime of any device has an exponential distribution with parameter 1. The concept of random hazard functions is also used in Gaver [5] and Arjas [6]. The intrinsic aging model of Çınlar and Özekici [4] is studied further in Çınlar *et al.* [7] to determine the conditions that lead to associated component lifetimes, as well as multivariate increasing failure rate (IFR) and new better than used (NBU) life distribution characterizations. It was also extended in Shaked and Shanthikumar [8] by discussions on several different models with multicomponent replacement policies. Lindley and Singpurwalla [9] discuss the effects of the random environment on the reliability of a system consisting of components that share the same environment. Although the initial state of the environment is random, they assume that it remains constant in time and components have exponential life distributions in each possible environment. This model is also studied by Lefèvre and Malice [10] to determine partial orderings on the number of functioning components and the reliability of k -out-of- n systems, for different partial orderings of the probability distribution on the environmental state. The association of the lifetimes of components subjected to a randomly varying environment is discussed in Lefèvre and Milhaud [11]. Singpurwalla and Youngren [12] also discuss multivariate distributions that arise in models where a dynamic environment affects the failure rates of the components.

Reliability models in random environments also provide a perfect opportunity to analyze mission-based or so-called phased-mission reliability systems. Our aim in this article is to present an example along this direction. These systems involve devices or machines that are designed to perform or assigned to missions consisting of a number of phases. The sequence as well as the durations of the phases may be random and, as in all random environment models, all stochastic and deterministic failure properties depend on the phases of the mission that is performed at a given time. Therefore, the random environmental process is the mission process in such models. A phased-mission consists of a number of stages or phases that must be successfully completed. These systems were introduced by Esary and Ziehms [13] and a vast literature has accumulated since then. The phases may be deterministic

2 Markov Renewal Processes in Reliability Modeling

or stochastic as in Kim and Park [14]. The components are either repairable or nonrepairable. Alam and Al-Saggaf [15] discuss a phased-mission system with **repairable components** where the repair activity begins as soon as a component fails. A case study involving spacecraft is provided by Mura and Bondavalli [16] where the mission consists of four basic phases: launch, hibernation, planet, and scientific observation. The reader is referred to these papers and the many references cited in them for various models, techniques, and applications on phased-mission systems.

Let X_n denote the n th phase of the mission and T_n denote the time at which the n th phase starts with $T_0 \equiv 0$. The main assumption is that the process $(X, T) = \{(X_n, T_n); n \geq 0\}$ is a Markov renewal process on the countable state space E with some semi-Markov kernel Q . The state space E is actually that of the process X and it is implicitly understood that the process T always takes values in $R_+ = [0, +\infty)$ since they denote times at which certain events occur. We refer the reader to Çinlar [17] for a more rigorous and detailed treatment of Markov renewal processes and theory. The Markov renewal property states that

$$\begin{aligned} P\{X_{n+1} = j, T_{n+1} - T_n \leq t | X_0, \dots, X_n; T_0, \dots, T_n\} \\ = P\{X_{n+1} = j, T_{n+1} - T_n \leq t | X_n\} \end{aligned} \quad (1)$$

where we suppose that the process is time homogeneous with the semi-Markov kernel

$$Q(i, j, t) = P\{X_{n+1} = j, T_{n+1} - T_n \leq t | X_n = i\} \quad (2)$$

for any $i, j \in E$ and $t \geq 0$. It is well known that X is a Markov chain on E with transition matrix $P(i, j) = P\{X_{n+1} = j | X_n = i\} = Q(i, j, +\infty)$. We further assume that the Markov renewal process has infinite lifetime so that $\sup_n T_n = +\infty$. The probabilistic structure of T is given by the conditional distributions

$$\begin{aligned} G(i, j, t) &= P\{T_{n+1} - T_n \leq t | X_n = i, X_{n+1} = j\} \\ &= \frac{Q(i, j, t)}{P(i, j)} \end{aligned} \quad (3)$$

for $P(i, j) > 0$. Moreover, it is easy to see that

$$F_i(t) = P\{T_1 \leq t | X_0 = i\} = \sum_{j \in E} Q(i, j, t) \quad (4)$$

denotes the distribution of the duration of phase i . Finally, the mission process $Y = \{Y_t; t \geq 0\}$ is the minimal semi-Markov process associated with (X, T) so that Y_t is the stage or phase of the mission at time t . More precisely, $Y_t = X_n$ whenever $T_n \leq t < T_{n+1}$.

To simplify the notation, for any event A we will let $P_i\{A\} = P\{A | X_0 = i\}$ denote the conditional probability of A given $X_0 = i$. The reliability of a mission-based system will be analyzed with two extreme repair policies: maximal repair and no repair. The system is replaced by a brand-new one at the beginning of each phase in the first case whereas no repair or replacement is done in the second case until the system fails. We discuss system and mission reliability with maximal repair in the second section. Mission reliability can be defined in different ways. We consider two alternatives where we focus on the probability of completing the first n phases successfully in the first one, and the probability of completing a given critical phase in the second alternative. These issues are discussed for the no repair case in the third section using intrinsic aging concepts.

Models with Maximal Repair

Suppose that the system performs the mission such that at the beginning of each phase it is replaced by a brand-new one. This simplifying assumption allows us to obtain various reliability measures quite easily by using the renewal property. It is clear that the probability of survival during a given phase depends on it, and we let

$$\bar{P}_i(t) = 1 - P_i(t) = P_i\{L > t | Y_s = i; s \in [0, t]\} \quad (5)$$

denote the survival probability of the system in phase i for t units of time where L is the lifetime of the system.

We can obtain another Markov renewal processes using (X, T) , which will be used during the analysis. Define a new Markov renewal process $(\tilde{X}, \tilde{T})$

through its minimal semi-Markov process $\tilde{Y}$ so that

$$\tilde{Y}_t = \begin{cases} Y_t & \text{if } t < L \\ \Delta & \text{if } t \geq L \end{cases} \quad (6)$$

where Δ is an absorbing state. This also implies that

$$\tilde{T}_n = \begin{cases} 0 & n = 0 \\ \inf\{t > T_{n-1} : \tilde{Y}_t \neq \tilde{Y}_{T_{n-1}}\} & n \geq 1 \end{cases} \quad (7)$$

and $\tilde{X}_n = \tilde{Y}_{\tilde{T}_n}$ for $n \geq 0$. Clearly, the state space of $(\tilde{X}, \tilde{T})$ is $\tilde{E} = E \cup \{\Delta\}$ and its semi-Markov kernel is

$$\begin{aligned} \tilde{Q}(i, k, ds) &= \begin{cases} \bar{P}_i(s) \tilde{Q}(i, k, ds) & \text{if } i, k \in E \\ \bar{F}_i(s) P_i(ds) & \text{if } i \in E, k = \Delta \\ 0 & \text{if } i, k = \Delta \end{cases} \end{aligned} \quad (8)$$

Note that $\tilde{Q}(\Delta, \Delta, t) = 0$ for every $t \geq 0$ and $\tilde{P}(\Delta, \Delta) = 1$. In plain words, the new process $\tilde{Y}$ is obtained by “stopping” or “killing” the process Y whenever the system fails at time L . At the time of failure, the process is dumped to the absorbing state Δ that denotes system failure. The state space is therefore extended by including this new state Δ . We can find the transition matrix of the Markov chain $\tilde{X}$ as

$$\begin{aligned} \tilde{P}(i, j) &= \tilde{Q}(i, j, \infty) = \int_0^\infty \tilde{Q}(i, j, ds) \\ &= \int_0^\infty \bar{P}_i(s) \tilde{Q}(i, j, ds) \end{aligned} \quad (9)$$

for $i, j \in E$, and

$$\tilde{P}(i, \Delta) = \int_0^\infty \bar{F}_i(s) P_i(ds) \quad (10)$$

for $i \in E$.

Suppose that one is interested in the successful completion of a given critical phase j of the mission. Letting

$$U_j = \inf\{t \geq 0; Y_t \neq Y_{t-} = j\} \quad (11)$$

denote the first time that the mission process leaves state j , we can now define another new Markov renewal process $(\bar{X}, \bar{T})$ as appropriate through its

minimal semi-Markov process $\bar{Y}$. The new process is defined by

$$\bar{Y}_t = \begin{cases} Y_t & \text{if } t < \min\{L, U_j\} \\ \Delta & \text{if } L \leq \min\{t, U_j\} \\ S & \text{if } U_j \leq \min\{t, L\} \end{cases} \quad (12)$$

so that we now extend E such that $\bar{E} = E \cup \{\Delta, S\}$. We let the semi-Markov mission process Y go to the absorbing state Δ as soon as the system fails before completing phase j or to the absorbing state S as soon as phase j is completed without failure. Thus, if $\bar{X}_n = \Delta$ or $\bar{X}_n = S$, then $\bar{T}_{n+1} = \infty$. If the minimal semi-Markov process associated with this Markov renewal process is $\bar{Y}$, then the probability of completing the critical phase j until time t is $P_i\{\bar{Y}_t = S\}$ if the initial state is i . The Markov renewal kernel of this process can be obtained as

$$\bar{Q}(i, k, ds) = \begin{cases} \tilde{Q}(i, k, ds) & i \in E - \{j\}, k \in E \\ \tilde{Q}(i, \Delta, ds) & i \in E, k = \Delta \\ F_j(ds) \bar{P}_j(s) & i = j, k = S \\ 0 & \text{otherwise} \end{cases} \quad (13)$$

Note that $\bar{Q}(S, S, t) = \bar{Q}(\Delta, \Delta, t) = 0$ for every $t \geq 0$, and $\bar{P}(S, S) = \bar{P}(\Delta, \Delta) = 1$. If $i \in E - \{j\}, k \in E$, then phase i is completed successfully before system failure and hence $\bar{Q}(i, k, ds) = \tilde{Q}(i, k, ds)$. If $i \in E$ and $k = \Delta$, then $\bar{Q}(i, k, ds)$ represents the probability of failure during phase i in the vicinity of time s , which means that the duration of phase i is longer than s units of time and a failure will occur in the vicinity of time s . Therefore, this probability is equal to $\tilde{Q}(i, \Delta, ds) = \bar{F}_i(s) P_i(ds)$. Moreover, $\bar{Q}(j, S, ds)$ represents the probability that the system will complete phase j in the vicinity of time s given that the system is in working condition at the beginning of phase j . This situation occurs if the duration of mission j is in the vicinity of time s and the system survives more than s units of time in these conditions; hence, $\bar{Q}(j, S, ds) = F_j(ds) \bar{P}_j(s)$. It is clear from the definition of the process $(\bar{X}, \bar{T})$ that the states S and Δ are absorbing states. Therefore, if the process gets into states S or Δ , it remains there forever where S now represents the “success” state and Δ represents the “failure” state.

4 Markov Renewal Processes in Reliability Modeling

System Reliability

System reliability is given by the probability that the system will function until time t . Let $f(i, t) = P_i \{L > t\}$ denote the desired probability. Then, conditioning on T_1

$$\begin{aligned} f(i, t) &= P_i \{L > t, T_1 > t\} + P_i \{L > t, T_1 \leq t\} \\ &= P_i \{L > t | T_1 > t\} P_i \{T_1 > t\} \\ &\quad + P_i \{L > t, T_1 \leq t\} = \bar{P}_i(t) \bar{F}_i(t) \\ &\quad + \sum_{j \in E} \int_0^t Q(i, j, ds) \bar{P}_i(s) f(j, t-s) \\ &= g(i, t) + \tilde{Q} * f(i, t) \end{aligned} \quad (14)$$

where $g(i, t) = \bar{P}_i(t) \bar{F}_i(t)$ and $\tilde{Q}(i, j, ds) = Q(i, j, ds) \bar{P}_i(s)$ for $i \in E$. Clearly, $f(\Delta, t) = g(\Delta, t) = 0$. Then, equation (14) is a Markov renewal equation and it has the unique solution $f = \tilde{R} * g$ so that

$$\begin{aligned} P_i \{L > t\} &= \sum_{j \in E} \int_0^t \tilde{R}(i, j, ds) g(j, t-s) \\ &= \sum_{j \in E} \int_0^t \tilde{R}(i, j, ds) \bar{P}_j(t-s) \bar{F}_j(t-s) \end{aligned} \quad (15)$$

where $\tilde{R} = \sum_{n=0}^{\infty} \tilde{Q}^n$ is the Markov renewal kernel corresponding to $\tilde{Q}$.

Mission Reliability

In a given application, it may be important to determine the probability that the system will complete the first n phases successfully. We will now focus on this issue and show that this probability can be calculated using a recursive formula and then obtain an explicit solution. We first find the probability that the first phase will be completed without failure. This can be done by conditioning on the next phase after the first one so that

$$P_i \{L > T_1\} = \sum_{j \in E} P_i \{L > T_1, X_1 = j\}$$

$$\begin{aligned} &= \sum_{j \in E} \int_0^{\infty} \bar{P}_i(s) Q(i, j, ds) \\ &= \int_0^{\infty} \bar{P}_i(s) F_i(ds) \end{aligned} \quad (16)$$

Now, we can write,

$$\begin{aligned} P_i \{L > T_{n+1}\} &= \sum_{j \in E} P_i \{L > T_{n+1}, X_1 = j\} \\ &= \sum_{j \in E} P_j \{L > T_n\} P_i \{X_1 = j, L > T_1\} \\ &= \sum_{j \in E} P_j \{L > T_n\} \int_0^{\infty} \bar{P}_i(s) Q(i, j, ds) \end{aligned} \quad (17)$$

which is a recursive relationship with the boundary condition $P_i \{L > T_0\} = 1$ for $n \geq 0$. Using equations (9) and (17), we have

$$P_i \{L > T_{n+1}\} = \sum_{j \in E} \tilde{P}(i, j) P_j \{L > T_n\} \quad (18)$$

Letting $f_n(i) = P_i \{L > T_n\}$, we can rewrite equation (18) as

$$f_{n+1} = \tilde{P} f_n \quad (19)$$

for $n \geq 0$ with the boundary condition $f_0 = 1$. Then, it is clear that $f_1 = \tilde{P} f_0$, $f_2 = \tilde{P} f_1 = \tilde{P}^2 f_0$, and, more generally, $f_n = \tilde{P} f_{n-1} = \tilde{P}^n f_0$ so that the solution is

$$f_n(i) = \tilde{P}^n f_0(i) = \sum_{j \in E} \tilde{P}^n(i, j) \quad (20)$$

It is also possible to obtain the same solution by noting that

$$P_i \{L > T_n\} = P_i \{\tilde{X}_n \in E\} = \sum_{j \in E} \tilde{P}^n(i, j) \quad (21)$$

since the n th phase of the mission is successfully completed if $\tilde{X}_n \neq \Delta$.

Critical Phase Reliability

For a complex system, a given phase can be more important than the others because of the overall objective of the mission. Therefore, the probability that this phase will be completed in a fixed period is

an important measure to represent the reliability of the system. To analyze this case, define

$$W_j(t) = \begin{cases} 1 & \text{if phase } j \text{ is completed before time } t \\ 0 & \text{otherwise} \end{cases} \quad (22)$$

where j is the critical phase. Then, using the definition of $(\bar{X}, \bar{T})$, the desired probability is

$$P_i \{W_j(t) = 1\} = P_i \{\bar{Y}_t = S\} \quad (23)$$

and, using Proposition (10.5.4) in [18], we have

$$P_i \{W_j(t) = 1\} = P_i \{\bar{Y}_t = S\} = \bar{R}(i, S, t) \quad (24)$$

where $\bar{R} = \sum_n \bar{Q}^n$ is the Markov renewal kernel corresponding to $\bar{Q}$.

Models with No Repair

In the previous section, we considered systems with maximal repair so that we had a brand-new system at the beginning of each phase. In this section, we remove this assumption and, hence, the system will deteriorate or get older in time. Therefore, the concept of “aging” comes into consideration. In this study, we will use the “intrinsic aging” model introduced by Çinlar and Özekici [4]. The analysis will be presented for a series system with m components, which requires that all components must function for the system to be functional.

Before the analysis, some new notation should be introduced. Let $H_k(i, t)$ be the cumulative hazard of component k at time t in phase i . Then, the intrinsic age of component k at time t is defined as $H_k(i, t)$ provided that the system performs phase i throughout $[0, t]$. The intrinsic aging rate of component k during phase i is defined as

$$r_k(i, a) = \frac{d}{dt} H_k(i, t) \big|_{t=\tau(x, a)} \quad (25)$$

at any age $a \geq 0$, where $\tau_k(i, a)$ is the time at which the intrinsic age of component k becomes a if the system performs phase i ; or

$$\tau_k(i, a) = \inf \{t \geq 0 : H_k(i, t) > a\} \quad (26)$$

Let $A_t(k)$ denote the intrinsic age process of component k . We assume that the intrinsic age process satisfies

$$\frac{dA_t(k)}{dt} = r_k(Y_t, A_t(k)) \quad (27)$$

Therefore, if the intrinsic age of component k at time s when phase i starts is $A_s(k) = a$, then after t units of time its age becomes

$$A_{s+t}(k) = h_k(i, a, t) = H_k(i, \tau_k(i, a) + t) \quad (28)$$

Let $B_0(k) = A_0(k)$ and define an embedded process $\{B_n(k)\}$ recursively through

$$B_{n+1}(k) = h(X_n, B_n(k), T_{n+1} - T_n) \quad (29)$$

for $n \geq 0$. Then, the intrinsic age of component k at time t is given by

$$A_t(k) = h(X_n, B_n(k), t - T_n) \quad (30)$$

whenever $T_n \leq t \leq T_{n+1}$. Let $L(k)$ and $\hat{L}(k)$ denote the lifetime and the intrinsic lifetime of component k respectively. Then,

$$\hat{L}(k) = A_{L(k)}(k) \quad (31)$$

for all k . Following Çinlar and Özekici [4], $\hat{L}(k)$ is exponentially distributed with rate 1 for all k and

$$\begin{aligned} P\{L(k) > t | A_0(k) = a(k)\} \\ &= P\{\hat{L}(k) > A_t(k) | A_0(k) = a(k)\} \\ &= E[e^{-(A_t(k) - a(k))}] \end{aligned} \quad (32)$$

Let A_t , a , $h(i, a, t)$, L , and $\hat{L}$ denote the vectors with elements $A_t(k)$, $a(k)$, $h_k(i, a, t)$, $L(k)$, and $\hat{L}(k)$ for all k , respectively. We let $F = R_+^m$ denote the collection of all nonnegative vectors where m is the number of components in the system. Each a in F represents a vector of intrinsic ages of all components. Assume that if b is a vector, then $b > x$ for a scalar x means that $b(k) > x$ for all k ; and if a, b are both vectors in F , then $b > a$ means that $b(k) > a(k)$ for all k . We let σ be a row vector with m entries which are all equal to 1, and

$$H(i, a, t; db) = \begin{cases} 1 & \text{if } h(i, a, t) = b \\ 0 & \text{otherwise} \end{cases} \quad (33)$$

To simplify our notation, for any event A we will let $P_{ia}\{A\} = P\{A | X_0 = i, A_0 = a, \hat{L} > a\}$ denote the

6 Markov Renewal Processes in Reliability Modeling

conditional probability of A given $X_0 = i$, $A_0 = a$, $\hat{L} > a$. Our analysis in the previous section used the fact that (X, T) is a Markov renewal process to obtain Markov renewal characterizations on various reliability measures. This analysis was possible because of the maximal repair assumption so that the system was brand new at the beginning of each phase. However, when this is not the case, we need to base our analysis on the new Markov renewal process $((X, B), T)$ that also includes information on the intrinsic ages of the components. The state space is now extended to $E \times F$.

System Reliability of a Series System

We first consider the system reliability of a series system that is performing a mission. In other words, we want to determine the probability that the system will work without failure until time t . Using a Markov renewal characterization, we define $f(i, a, t) = P_{ia} \{L > t\}$ and obtain

$$\begin{aligned} P_{ia} \{L > t\} &= P_{ia} \{L > t, T_1 > t\} \\ &+ P_{ia} \{L > t, T_1 \leq t\} = \bar{F}_i(t) e^{-\sigma(h(i,a,t)-a)} \\ &+ \sum_{j \in E} \int_{F \times [0,t]} Q(i, j, ds) H(i, a, s; db) \\ &\times e^{-\sigma(b-a)} f(j, b, t-s) \end{aligned} \quad (34)$$

which is a Markov renewal equation of the form $f = g + \hat{Q} * f$, where

$$g(i, a, t) = \bar{F}_i(t) e^{-\sigma(h(i,a,t)-a)} \quad (35)$$

and

$$\begin{aligned} \hat{Q}(i, a, j, db, ds) &= Q(i, j, ds) H(i, a, s; db) \\ &\times e^{-\sigma(b-a)} \end{aligned} \quad (36)$$

It is clear that $\hat{Q}$ is a semi-Markov kernel on the extended state space $\tilde{E} \times F$ and the Markov renewal equation has the unique solution $f = \hat{R} * g$ such that

$$\begin{aligned} P_{ia} \{L > t\} &= \sum_{j \in \tilde{E}} \int_{F \times [0,t]} \hat{R}(i, a; j, db; ds) \\ &\times \bar{F}_j(t-s) e^{-\sigma(h(j,b,t-s)-b)} \end{aligned} \quad (37)$$

where $\hat{R} = \sum_n \hat{Q}^n$ is the Markov renewal kernel corresponding to $\hat{Q}$.

Mission Reliability of a Series System

We now focus on computing mission reliability involving the first n phases of the mission. We first find the probability that the first phase will be completed by conditioning on the next phase so that

$$\begin{aligned} P_{ia} \{L > T_1\} &= \sum_{j \in E} P_{ia} \{L > T_1, X_1 = j\} \\ &= \sum_{j \in E} P_{ia} \{L > T_1 | X_1 = j\} P(i, j) \end{aligned} \quad (38)$$

Note that

$$\begin{aligned} P_{ia} \{L > T_1 | X_1 = j\} &= \int_{F \times [0,\infty)} P_{ia} \{L > T_1, T_1 \in ds, B_1 \in db | X_1 = j\} \\ &= \int_{F \times [0,\infty)} e^{-\sigma(b-a)} G(i, j, ds) H(i, a, s; db) \end{aligned} \quad (39)$$

Combining equations (38) and (39), we obtain

$$\begin{aligned} P_{ia} \{L > T_1\} &= \sum_{j \in E} \int_{F \times [0,\infty)} Q(i, j, ds) \\ &\times e^{-\sigma(b-a)} H(i, a, s; db) \end{aligned} \quad (40)$$

Similarly, we can now obtain a recursive relationship

$$\begin{aligned} P_{ia} \{L > T_{n+1}\} &= \sum_{j \in E} P_{ia} \{L > T_{n+1} | X_1 = j\} P(i, j) \\ &= \sum_{j \in E} \int_{F \times [0,\infty)} P_{ia} \{L > T_{n+1}, T_1 \in ds, \\ &\quad B_1 \in db | X_1 = j\} P(i, j) \\ &= \sum_{j \in E} \int_{F \times [0,\infty)} e^{-\sigma(b-a)} Q(i, j, ds) \\ &\quad \times H(i, a, s; db) P_{jb} \{L > T_n\} \end{aligned} \quad (41)$$

for $n \geq 0$. Let $\hat{Q}(i, a; j, db; ds) = Q(i, j, ds) H(i, a, s; db) e^{-\sigma(b-a)}$, and define

$$\hat{P}(i, a; j, db) = \hat{Q}(i, a; j, db; \infty)$$

$$= P_{ia} \{X_1 = j, B_1 \in db\} \quad (42)$$

and

$$\begin{aligned} \hat{P}^n(i, a; j, db) &= \sum_{j \in E} \int_F \hat{P}^{n-1}(i, a; k, dc) \hat{P}(k, c; j, db) \\ &= P_{ia} \{X_n = j, B_n \in db\} \end{aligned} \quad (43)$$

for $n \geq 1$.

Then, it follows from equation (40) that

$$\begin{aligned} P_{ia} \{L > T_1\} &= \sum_{j \in E} \int_{F \times [0, \infty)} \hat{Q}(i, a; j, db; ds) \\ &= \sum_{j \in E} \int_F \hat{Q}(i, a; j, db; \infty) \\ &= \sum_{j \in E} \int_F \hat{P}(i, a; j, db) \end{aligned} \quad (44)$$

Now, using induction, we will show that

$$P_{ia} \{L > T_n\} = \sum_{j \in E} \int_F \hat{P}^n(i, a; j, db) \quad (45)$$

for every $n \geq 1$. We have already shown that equation (45) holds for $n = 1$. Suppose that

$$P_{ia} \{L > T_k\} = \sum_{j \in E} \int_F \hat{P}^k(i, a; j, db) \quad (46)$$

for all $k \leq n - 1$. Then, using equations (41) and (46),

$$\begin{aligned} P_{ia} \{L > T_n\} &= \sum_{j \in E} \int_{F \times [0, \infty)} \hat{Q}(i, a; j, db; ds) P_{jb} \{L > T_{n-1}\} \\ &= \sum_{j \in E} \int_F \hat{P}(i, a; j, db) \sum_{k \in E} \int_F \hat{P}^{n-1}(j, b; k, dc) \\ &= \sum_{j \in E} \int_F \hat{P}^n(i, a; j, db) \end{aligned} \quad (47)$$

Critical Phase Reliability of a Series System

Suppose that there is a critical phase j and we are interested in computing the probability

$P_{ia} \{W_j(t) = 1\}$ that phase j will be completed successfully by time t . Using a similar approach as in the critical reliability part of the previous section, we note that the process $\bar{Y}$ defined by equation (12) is a semiregenerative process. In this case, the semi-Markov kernel corresponding to the Markov renewal process $((\bar{X}, B), \bar{T})$ is given by

$$\bar{Q}(i, a; k, db; ds) = \begin{cases} Q(i, k, ds) H(i, a, s; db) \times e^{-\sigma(b-a)} & \text{if } i \in E - \{j\}, \\ & k \in E \\ \bar{F}_i(s) H(i, a, s; db) U_{ia}(ds) & \text{if } i \in E, k = \Delta \\ F_j(ds) H(i, a, s; db) e^{-\sigma(b-a)} & \text{if } i = j, k = S \\ 0 & \text{otherwise} \end{cases} \quad (48)$$

where

$$U_{ia}(s) = 1 - e^{-\sigma(h(i, a, s) - a)}. \quad (49)$$

Note that $\bar{Q}(S, a; S, db; t) = \bar{Q}(\Delta, a; \Delta, db; t) = 0$ trivially for every $t \geq 0$, $a, b \in F$ and $\bar{P}(S, a; S, da) = \bar{P}(\Delta, a; \Delta, da) = 1$ for every $a \in F$. We now find the probability $f(i, a, t) = P_{ia} \{\bar{Y}_t = j, A_t \in db\}$ for some $j \in \bar{E}$ and $b \in F$. Using Markov renewal theory,

$$\begin{aligned} f(i, a, t) &= P_{ia} \{\bar{Y}_t = j, A_t \in db, \bar{T}_1 > t\} \\ &\quad + P_{ia} \{\bar{Y}_t = j, A_t \in db, \bar{T}_1 \leq t\} \\ &= I(i, j) I(a, b) q(i, a, t) \\ &\quad + \sum_{l \in \bar{E}} \int_{F \times [0, t]} \bar{Q}(i, a; l, dc; ds) \\ &\quad \times P_{lc} \{\bar{Y}_{t-s} = j, A_{t-s} \in db\} \\ &= I(i, j) I(a, b) q(i, a, t) \\ &\quad + \sum_{l \in \bar{E}} \int_{F \times [0, t]} \bar{Q}(i, a; l, dc; ds) \\ &\quad \times f(l, c, t-s) \end{aligned} \quad (50)$$

where

$$\begin{aligned} q(i, a, t) &= P_{ia} \{\bar{T}_1 > t\} \\ &= 1 - \sum_{l \in \bar{E}} \int_F \bar{Q}(i, a; l, db; t) \end{aligned} \quad (51)$$

We have a Markov renewal equation $f = g + \bar{Q} * f$ with

$$g(i, a, t) = I(i, j) I(a, b) q(i, a, t) \quad (52)$$

Following Proposition A.2 in [4], equation (50) has a unique solution

$$\begin{aligned} f(i, a, t) &= P_{ia} \{ \bar{Y}_t = j, A_t \in db \} \\ &= \sum_{l \in \bar{E}} \int_{F \times [0, t]} \bar{R}(i, a; l, dc; ds) g(l, c, t - s) \\ &= \int_{[0, t]} \bar{R}(i, a; j, db; ds) q(j, b, t - s) \end{aligned} \quad (53)$$

where $\bar{R} = \sum_n \bar{Q}^n$ is the Markov renewal kernel corresponding to $\bar{Q}$.

Then, using equation (53)

$$\begin{aligned} P_{ia} \{ W_j(t) = 1 \} &= \int_F P_{ia} \{ \bar{Y}_t = j, A_t \in db \} \\ &= \int_{F \times [0, t]} \bar{R}(i, a; j, db; ds) \\ &\quad \times q(j, b, t - s) \end{aligned} \quad (54)$$

Warranty Cost Analysis

Introduction

New products have been appearing in the market at an ever-increasing rate due to the ever-increasing pace of technological innovation. Each generation of products typically incorporates new features and is more complex than the one it replaces. With the increase in complexity and the use of new materials and design methodologies, the reliability of products is of concern to buyers. One way for the manufacturer to assure the buyer that the product will perform satisfactorily is to offer a warranty with the sale of the product. In very simple terms, the warranty assures the buyer that the manufacturer will either repair or replace items that do not perform satisfactorily or refund a fraction or the whole of the sale price. Offering warranty results in additional costs to the manufacturer. The manufacturer must assess this cost very early in the product development stage in order to make decisions with regard to desired product reliability and appropriate product pricing.

This article deals with **warranty cost** analysis for some simple **warranty policies**. This involves building models for claims under warranty, taking into account the reliability of the product. The outline of the article is as follows. The section titled “Product Warranty” looks at the basic concept of a warranty and provides a few examples of commonly used consumer warranties. The cost of warranty is impacted by product reliability in an obvious fashion. Some key reliability results needed in assessing this impact are summarized in the section titled “Product Reliability”. Probabilistic results used in modeling warranty costs are given in the section titled “Warranty Cost Analysis” and applied to analysis of cost per unit sold and **life cycle cost** of warranty in the sections titled “Modeling Warranty Cost per Unit Sold” and “Warranty Cost over Life Cycle” respectively.

Product Warranty

Warranty Concept

A warranty is a contractual agreement between the buyer and the manufacturer (or seller) that is entered

into upon sale of the product or service. The purpose of a warranty is to establish liability of the manufacturer in the event that an item fails or is unable to perform its intended function when properly used. The warranty (often referred to as the *base warranty*) is an integral part of the sale (a service bundled with the product) and is factored into the price. In contrast, extended warranty is a service contract that a buyer might purchase separately to extend the warranty coverage once the base warranty expires.

Warranties are an integral part of nearly all consumer and commercial purchases and also of many government transactions that involve product purchases. In such transactions, warranties serve a somewhat different purpose for the buyer and the manufacturer. For a more detailed discussion of the role of warranty from the perspectives of buyers and manufacturers see [1]. There are many aspects to warranty, and these have been studied by researchers from different disciplines. A discussion of these can be found in [2].

Classification of Warranties

A taxonomy for warranty classification was first proposed by Blischke and Murthy [3]. The first criterion for classification is whether the manufacturer is required to carry out further product development (for example, to improve product reliability) subsequent to the sale of the product. Policies that do not involve such further product development can be further divided into two groups, the first consisting of policies applicable for single-item sales, and the second, policies used in the sale of groups of items (called *lot* or *batch sales*).

Policies in the first group can be subdivided into two subgroups, based on whether the policy is renewing or nonrenewing. For renewing policies, the warranty period begins anew with each replacement, while for nonrenewing policies the replacement (or repaired) item assumes the remaining warranty time of the item it replaced. A further subdivision comes about in that warranties may be classified as “simple” or “combination”. The commonly used consumer warranties featuring free-replacement warranty (FRW) and replacement at *pro rata* cost (PRW), discussed in the next section, are simple policies. A combination policy is a simple policy combined with some additional features or a policy that combines the terms of two or more simple policies. Each of these

2 Warranty Cost Analysis

four groupings can be further subdivided into two subgroups based on whether the policy is one- or two- (or higher)-dimensional. A one-dimensional policy is one that is most often based on either time or age of the item, but could instead be based on usage. An example is a one-year warranty on a television with the option for buyers to purchase extended warranty coverage. In contrast, a two-dimensional policy is based on time or age as well as usage. An example is an automobile with a two-dimensional warranty with a time limit of 3 years and usage limit of 30 000 miles. The warranty expires when one of the limits is exceeded.

Some Simple Warranty Policies

Three simple warranty policies are defined in this section. The cost analysis for each of these is given in the later sections.

Policy 1: One-Dimensional (1-D) Nonrenewing Free-Replacement Warranty (FRW). The manufacturer agrees to repair or provide replacements for failed items free of charge up to a time W from the time of the initial purchase. The warranty expires at time W after purchase.

Typical applications of this warranty are consumer products, ranging from inexpensive items such as photographic film to relatively expensive repairable items such as automobiles, and on expensive nonrepairable items such as microchips and other electronic components.

Policy 2: One-Dimensional Nonrenewing Pro rata Warranty (PRW). The manufacturer agrees to refund a fraction of the purchase price if the item fails before time W from the time of the initial purchase. The buyer is not constrained to buy a replacement item.

Under the *pro rata* warranty (PRW), the refund given depends on the age of the item at failure. In the most common form of PRW, the refund is determined by the linear relationship $q(x) = [(W - x)/W]P$, where W is the warranty period, x is the age at failure, P is the sale price, and $q(\cdot)$, called the *rebate function*, is the amount of refund. Typically, these policies are offered on relatively inexpensive nonrepairable products such as batteries, tires, ceramics, and so on.

Policy 3: Two-Dimensional (2-D) Nonrenewing FRW. The manufacturer agrees to repair or provide a replacement for failed items free of charge up to a time W from the time of initial purchase (limit on time) or up to a usage U (limit on usage), whichever occurs first.

Product Reliability

The modeling of first failures is different from that of subsequent failures. In the latter case, the result depends on whether the failed item is repaired or replaced by a new item.

One-Dimensional Failure Modeling

First Failure. The time to first failure, T , is a random variable that can assume values in the interval $[0, \infty)$, with distribution function

$$F(t) = P\{T \leq t\}, \quad 0 \leq t < \infty \quad (1)$$

The *density function* (if $F(t)$ is differentiable) is given by $f(t) = dF(t)/dt$. The *reliability* (of the item) is given by the survivor function

$$S(t) = P\{T > t\} = 1 - P\{T \leq t\} = 1 - F(t) \quad (2)$$

The failure rate function (or hazard function) $h(t)$ associated with $F(t)$ is defined as

$$h(t) = \frac{f(t)}{1 - F(t)} \quad (3)$$

Subsequent Failures. When a repairable component fails, it can either be repaired or replaced by a new component. In the case of a nonrepairable component, the only option is to replace the failed component with a new item. Since failures occur in an uncertain manner, the number of components needed over a given time interval is a nonnegative, integer-valued random variable. The distribution of this variable depends on the failure distribution of the component, the actions (repair or replace) taken after each failure, and, if repaired, the type of repair. The number of failures $N(t)$ over the interval $[0, t]$, starting with a new component at $t = 0$, can be modeled as a *counting process*.

Nonrepairable Item. In the case of a nonrepairable component, every failure results in the replacement

of the failed component by a new item. If the time to replace a failed component by a new one is small relative to the mean time to failure, then it can be ignored. In this case, the number of failures (replacements) over time is given by a *renewal process* and the mean number of failures over $[0, t]$, is given by the *renewal integral equation*:

$$M(t) = F(t) + \int_0^t M(t-t') dF(t') \quad (4)$$

Repairable Item. There are different types of repairs. With *minimal repair* (see **General Minimal Repair Models**), the failure rate after repair is the same as the failure rate of the item immediately before it failed [4]. With *imperfect repair* (see **Imperfect Repair**), the failure rate after repair is less than that just before failure but not as good as that for a new component.

With minimal repair and the repair time negligible in relation to the mean time between failures, failures over time occur according to a *nonhomogeneous Poisson process* [5]. The mean number of failures over $[0, t]$ is given by

$$E[N(t)] = \Lambda(t) = \int_0^t h(x) dx \quad (5)$$

In the case of imperfect repair, the analysis is more complicated. See [6] and references therein for additional details.

Two-Dimensional Failure Modeling

There are two approaches to modeling failures in the 2-D case.

Approach 1: 1-D Approach. The two-dimensional problem is effectively reduced to a one-dimensional problem by treating usage as a function of age.

First Failure. Let $Z(t)$ denote the usage of the item at age t and assume that it is a linear function of t of the form

$$Z(t) = Rt \quad (6)$$

where $R, 0 \leq R < \infty$, represents the usage rate and is a nonnegative random variable with a distribution function $G(r)$ and a density function $g(r)$.

The hazard function, conditional on $R = r$, is denoted $h(t|r)$. Various forms of $h(t|r)$ have been proposed, including the linear case given by

$$h(t|r) = \theta_0 + \theta_1 r + \theta_2 t + \theta_3 Z(t) \quad (7)$$

The conditional distribution function of time to first failure is given by

$$F(t|r) = 1 - \exp \left\{ - \int_0^t h(u|r) du \right\} \quad (8)$$

On removing the conditioning, we have the distribution function of time to first failure given by

$$F(t) = \int_0^\infty \left(1 - \exp \left\{ - \int_0^t h(u|r) du \right\} \right) g(r) dr \quad (9)$$

Subsequent Failures. Under minimal repair, the failures over time occur according to a nonhomogeneous Poisson process [7] with **intensity function** $\lambda(t|r) = h(t|r)$. Under perfect repair, the failures occur according to the renewal process associated with $F(t|r)$.

The bulk of the literature deals with a linear relationship between usage and age. See, for example, [1, 8, and 9]. For applications, see [10], which deals with motorcycle failures under warranty, and [8] and [11], which deal with automobile warranty data analysis.

Approach 2: 2-D Approach. *First Failure.* Let T and X denote the item age and usage at first failure. Both of these are random variables. T and X are modeled jointly by the bivariate distribution function:

$$F(t, x) = P\{T \leq t, X \leq x\}; \quad t \geq 0, x \geq 0 \quad (10)$$

The survivor function is given by

$$\begin{aligned} \bar{F}(t, x) &= \Pr\{T > t, X > x\} \\ &= \int_t^\infty \int_x^\infty f(u, v) dv du \end{aligned} \quad (11)$$

If $F(t, x)$ is differentiable in both arguments, the bivariate failure density function is given by

$$f(t, x) = \frac{\partial^2 F(t, x)}{\partial t \partial x} \quad (12)$$

Subsequent Failures. In the case of nonrepairable items, failed items are replaced by new ones. In

4 Warranty Cost Analysis

this case, failures occur according to a 2-D renewal function [4] and the expected number of failures over $[0, t) \times [0, x)$ is given by the solution of the two-dimensional integral equation:

$$M(t, x) = F(t, x) + \int_0^t \int_0^x M(t - u, x - v) \times f(u, v) dv du \quad (13)$$

Warranty Cost Analysis

Two types of costs are of interest to the manufacturer: (a) expected cost per unit and (b) expected cost over the product life cycle.

Expected Cost per Unit Sold

Whenever a failed item is returned for rectification action under warranty, the manufacturer incurs various costs – handling, material, labor, facilities, and so on. These costs are random variables. The total cost of servicing all **warranty claims** for an item over the warranty period is the sum of a random number of such individual costs, since the number of claims over the warranty period is also random. The expected warranty service cost per unit is needed in deciding the selling price of the item.

Expected Cost over the Life Cycle of a Product

From a marketing perspective, the product life cycle, L , is the period from the instant a new product is launched to the instant it is withdrawn from the market. Over the product life cycle, product sales (first and repeat purchases) occur over time in a dynamic manner. The manufacturer must service the warranty claims with each such sale. In the case of products sold with one-dimensional nonrenewing warranty, this period is $L + W$, where W is the warranty period.

The expected cost incurred over $[t, t + \delta t)$ depends on the sales over the interval $[t - \psi, t)$, where

$$\psi = \max\{0, t - W\} \quad (14)$$

Sales over time can be modeled either by a continuous function (appropriate for large-volume sales) or a point process (appropriate for small-volume sales).

Assume that the sales rate is given by $s(t)$, $0 \leq t \leq L$, so that total sales S over the life cycle is

$$S = \int_0^L s(t) dt \quad (15)$$

Assumptions

In developing tractable and reasonable warranty cost models, various assumptions regarding the process are made. These typically include the following:

1. All consumers are alike in their usage. This can be relaxed by dividing consumers into two or more groups of similar usage patterns.
2. All items are statistically similar. This can be relaxed by including two types of items (conforming and nonconforming) to take into account quality variations in manufacturing.
3. Whenever a failure occurs, it results in an immediate claim. Relaxing this assumption involves modeling the delay time between failure and claim.
4. All claims are valid. This can be relaxed by assuming that a fraction of the claims is invalid, either because the item was used in a mode not covered by the warranty or because it was a bogus claim.
5. The time to rectify a failed item (either through repair or replacement) is sufficiently small in relation to the mean time between failures so that it can be approximated as being zero.
6. The manufacturer has the logistic support (spares and facilities) needed to carry out rectification actions without delays.
7. The cost of each rectification under warranty (repair or replacement) is modeled by the following cost parameters:

C_m : Cost of replacing a failed unit by a new unit (manufacturing cost per unit)

C_h : Handling cost per claim

C_r : Average cost of each minimal repair

8. The product life cycle, L , is modeled as a deterministic variable. One can easily relax this assumption and treat it as a random variable with a specified distribution.
9. All model parameters (costs and the various distributions involved) are known.

Modeling Warranty Cost per Unit Sold

Cost Analysis of Policy 1

Replace by New. Since failures under warranty are rectified instantaneously through replacement by new items, the number of failures over the period $[0, t)$, $N(t)$, is characterized by a renewal process with time between renewals distributed according to $F(t)$. As a result, the cost $\tilde{C}(W)$ to the manufacturer over the warranty period W is a random variable given by

$$\tilde{C}(W) = [C_m + C_h][N(W)] \quad (16)$$

The expected number of failures over the warranty period is

$$E[N(W)] = M(W) \quad (17)$$

where $M(t)$ is the renewal function given by equation (4). As a result, the expected warranty cost per unit to the manufacturer is

$$C(W) = [C_m + C_h]M(W) \quad (18)$$

Minimal Repair. Failures over the warranty period occur according to a nonhomogeneous Poisson process with intensity function equal to the failure rate $r(t)$ and the expected warranty cost to the manufacturer is

$$C(W) = [C_r + C_h] \int_0^W r(x) dx \quad (19)$$

Cost Analysis of Policy 2

In the case of linear rebate function

$$q(x) = \begin{cases} (1 - x/W)P & 0 \leq x < W \\ 0 & \text{otherwise} \end{cases} \quad (20)$$

the warranty cost to the manufacturer is

$$\tilde{C}(W) = C_h + q(T) \quad (21)$$

where T is the lifetime of the item supplied. As a result, the expected cost per unit to the manufacturer is

$$C(W) = E[\tilde{C}(W)] = C_h F(W) + \int_0^W q(x) f(x) dx \quad (22)$$

Using equation (20) in equation (22) and carrying out the integration, we have

$$C(W) = C_h F(W) + P \left[F(W) - \frac{\mu_W}{W} \right] \quad (23)$$

where

$$\mu_W = \int_0^W t f(t) dt \quad (24)$$

is the *partial expectation* of T .

Cost Analysis of Policy 3

As mentioned in the section titled “Approach 1: 1-D Approach” one can use two different approaches to modeling failures. Approach 1 is more appropriate for repairable products (with minimal repair) and Approach 2, for nonrepairable products.

Approach 1. The product is repairable, and the manufacturer rectifies all failures under warranty through minimal repair. In this case, the distribution of failures over the warranty period can be characterized by an intensity function $\lambda(t|r)$. Conditional on $R = r$, we assume a linear intensity function given by equation (7).

Note that conditional on $R = r$, the warranty expires at time W if the usage rate r is less than γ , where

$$\gamma = \frac{U}{W} \quad (25)$$

and at time t_r given by

$$t_r = \frac{U}{r} \quad (26)$$

if the usage rate $r > \gamma$. The expected numbers of failures over the warranty period for these two cases are given by

$$E[N(W, U)|r] = \int_0^W \lambda(t|r) dt \quad \text{and} \quad (27)$$

$$E[N(W, U)|r] = \int_0^{t_r} \lambda(t|r) dt$$

respectively. On removing the conditioning, we have the expected number of failures during warranty and, using this, we find the expected warranty cost to be

$$C(W, U) = [C_r + C_h] \left\{ \int_0^\gamma \left[\int_0^W \lambda(t|r) dt \right] g(r) dr + \int_\gamma^\infty \left[\int_0^{t_r} \lambda(t|r) dt \right] g(r) dr \right\} \quad (28)$$

Approach 2. The product is nonrepairable and the manufacturer rectifies all failures under warranty through replacement by a new product. In this case, the number of failures over the warranty region is given by a 2-D renewal process and the expected warranty cost is given by

$$C(W, U) = [C_m + C_h]M(W, U) \quad (29)$$

where $M(W, U)$ is obtained from equation (13).

Warranty Cost over Life Cycle

Consider the case where the product is nonrepairable and the life cycle L exceeds the warranty period W . Since the manufacturer must provide a refund or replacements for items that fail before reaching age W , and since the last sale occurs at or before time L , the manufacturer has an obligation to service warranty claims over the interval $[0, L + W]$. Life cycle costs for Policies 1 and 2 will be considered. Some results for Policy 3 can be found in Blischke and Murthy [1, Sections 8.3.1 and 8.4.1].

Cost Analysis for Policy 1

Since failed items are replaced by new ones over the warranty period, the demand for spares in the interval $[t, t + \delta t)$ is due to failure of items sold in the period $[\psi, t)$ where ψ is given by equation (14). It can be shown (details of derivation can be found in Chapter 9 of [1]) that the expected demand rate for spares at time t , $\rho(t)$, is given by

$$\rho(t) = \int_{\psi}^t s(x)m(t-x) dx \quad (30)$$

where $m(t)$ is the renewal density function given by

$$m(t) = \frac{dM(t)}{dt} = f(t) + \int_0^t m(t-t')f(t') dt' \quad (31)$$

The expected total number of spares required to service the warranty over the product life cycle, $ETNS$, is given by

$$ETNS = \int_0^{L+W} \rho(t) dt \quad (32)$$

and the total expected warranty cost over the product life cycle is given by

$$LC(W, L) = [C_m + C_h] \int_0^{W+L} \rho(t) dt \quad (33)$$

Cost Analysis for Policy 2

Under Policy 2 the manufacturer refunds a fraction of the sale price on failure of an item within the warranty period. In order to carry this out, the manufacturer must set aside a fraction of the sale price. This is called *warranty reserving*. We assume a linear rebate function. The rebate over the interval $[t, t + \delta t)$ is due to failure of items that are sold in the interval $[t - \psi, t)$, where ψ is given by equation (14). Let $v(t)$ denote the expected refund rate (i.e. the amount refunded per unit time) at time t . Then it is easily shown that

$$v(t) = P \int_{\psi}^t s(x) \left(\frac{t-t'}{W} \right) f(t-t') dt' \quad (34)$$

for $0 \leq t \leq (W + L)$. (For details, see Chapter 9 of [1].) The expected total reserve (ETR) needed to service the warranty over the product life cycle is given by

$$LC(W, L) = \int_0^{W+L} v(t) dt \quad (35)$$

Concluding Remarks

The cost analysis of many other types of warranty policies can be found in [1] and in more recent papers; references to some of these can be found in [12]. This type of analysis is carried out during the front-end (feasibility) stage of the new product development process. The model selection and parameter values are based on similar products, expert judgment (see **Expert Opinion in Reliability**), and so on. For more on this, see [13], which looks at warranty management from a product life cycle perspective. Once the product is launched, warranty claims provide data for assessing the models and updating the warranty cost estimates. For more on this, relevant references can be found in [12] and [13].

Age-Dependent Minimal Repair and Maintenance

Introduction

It is of great importance to avoid the failure of complex systems during actual operation when such an event is costly and/or dangerous. In such situations, one important area of interest in reliability theory is the study of various **maintenance policies** in order to reduce the operating cost and the risk of a catastrophic breakdown.

Maintenance involves planned and unplanned actions carried out to retain a system in or restore it to an acceptable operating condition. One important research area in reliability is the study of various maintenance policies in order to prevent the occurrence of system failure and improve **system availability**. Maintenance can be classified into two major categories: corrective or preventive. Corrective maintenance (CM) is any maintenance that occurs when the system is failed. Preventive maintenance (PM) is any maintenance that occurs when the system is operating. In this article, we think that maintenance can be further classified according to the degree to which the operating conditions of an item is restored by maintenance in the following two ways (Pham and Wang [1]):

1. *Perfect repair or perfect maintenance* – a maintenance action that restores the system operating condition to as good as new. Generally, replacement of a failed system by a new one is a perfect repair.
2. *Minimal repair or minimal maintenance* – a maintenance action that restores the system to the failure rate it had when it failed; that is, after maintenance the system operating state is often called *as bad as old*.

Optimal maintenance policies aim to provide optimum system reliability/availability and safety performance at lowest possible maintenance costs.

Two policies, of particular note, are the age-replacement maintenance policy and the block-replacement maintenance policy. In the age-replacement maintenance policy (see Barlow and

Hunter [2] for example), an operating system is replaced at age T or at failure, whichever occurs first. This model has been generalized by Glasser [3], Beichelt [4], Tahara and Nishida [5], Muth [6], Cleroux *et al.* [7], Nakagawa and Kowada [8], Bai and Yun [9], Berg *et al.* [10], Block *et al.* [11], Sheu *et al.* [12], and Sheu [13]. In the block-replacement maintenance policy (see Barlow and Proschan [14]), an operating system is replaced by a new one at times kT , $k = 1, 2, 3, \dots$ and at failures. Such a policy is rather wasteful, since sometimes almost-new systems are replaced. To overcome this undesirable feature, various modifications have been advocated to reduce the wastage, see Barlow and Hunter [2], Beichelt [15], Nakagawa [16, 17], Boland and Proschan [18], Boland [19], Nguyen and Murthy [20], Berg and Cleroux [21], Abdel-Hameed [22], Ait Kadi and Cleroux [23], Sheu [13, 24, 25], Ait Kadi *et al.* [26], and Chien and Sheu [27]. Moreover, Makabe and Morimura [28–30] also proposed the new replacement maintenance model in which a system is replaced at the n th failure and discussed the optimum policy. This model has been generalized by Morimura [31], Nakagawa [16, 32], Nakagawa and Kowada [8], and Park [33, 34], Sheu *et al.* [12], Sheu and Griffith [35], Sheu [36], and Chien *et al.* [37].

In this article, we present two PM policies for a complex system with age-dependent minimal repair and general random repair costs. Introducing costs due to minimal repair as well as planned and unplanned replacements, we develop the expected cost per unit time in the long run as a criterion of optimality and seek the optimum replacement policies by minimizing that cost. Under certain conditions, the existence and uniqueness of the minimum-cost policy is shown and discussed. Various special cases are presented. Finally, numerical examples are given.

Mathematical Formulation

Preliminaries

A system has two types of failures when it fails at age z . Type I failure (minor failure) occurs with probability $q(z)$ and is corrected with minimal repair, and where type II failure (catastrophic failure) occurs with probability $p(z) = 1 - q(z)$ the system has to be replaced. Minimal repair means that the repaired system is returned to the same condition as it was,

2 Age-Dependent Minimal Repair and Maintenance

i.e., the failure rate of the repaired system remains the same as it was just prior to failure. Assume that the system has a failure time distribution $F(x)$ with finite mean μ and density $f(x)$. Then, the failure rate (or the hazard rate) is $r(x) = f(x)/\bar{F}(x)$ and the cumulative hazard is $R(x) = \int_0^x r(y) dy$, which has a relation $\bar{F}(x) = \exp\{-R(x)\}$, where $\bar{F}(x) = 1 - F(x)$. It is further assumed that the failure rate $r(x)$ is continuous, monotone increasing, and remains undisturbed by minimal repair.

In this article, two general maintenance replacement policies are separately considered in which minimal repair or replacement takes place according to the following scheme.

Policy 1 ((n, T) policy) A system is replaced at age T or at the n th type I failure or at the first type II failure, whichever occurs first.

Policy 2 ((t, T) policy) A system is replaced at the first type II failure before age t or the first failure after age t or at age T , whichever occurs first.

For operating a system in an infinite time span, let U_i^* denote the length of the i th successive replacement cycle for $i = 1, 2, 3, \dots$. Let V_i^* denote the operational cost over the renewal interval U_i^* . Thus, $\{(U_i^*, V_i^*)\}$ constitutes a renewal reward process. The pairs (U_i^*, V_i^*) , $i = 1, 2, 3, \dots$ are independent and identically distributed. If $D(z)$ denotes the expected cost of the operating system over the time interval $[0, z]$, then it is well known that

$$\lim_{z \rightarrow \infty} \frac{D(z)}{z} = \frac{E(V_1^*)}{E(U_1^*)} \quad (1)$$

(see e.g., Ross [38, p. 52]).

In order to derive the expressions for $E(U_1^*)$ and $E(V_1^*)$, we must describe in more detail the failure process which governs the cost over the interval $[0, U_1^*]$. Consider a nonhomogeneous **Poisson process** $\{N(t), t \geq 0\}$ with intensity $r(t)$ and successive arrival times $S_1, S_2, \dots$. At time S_n a coin is flipped, the outcome is designated by δ_n which takes the value one (head) with probability $p(S_n)$ and the value zero (tail) with probability $q(S_n)$. Let $L(t) = \sum_{n=1}^{N(t)} \delta_n$ and $M(t) = N(t) - L(t)$. Then it can be shown that the process $\{L(t), t \geq 0\}$ and $\{M(t), t \geq 0\}$ are independent nonhomogeneous Poisson process with respective intensities $p(t)r(t)$ and $q(t)r(t)$ (see e.g., Savits [39]). This is similar to the classical decomposition of a Poisson process for constant p . Let Y_1

denote the waiting time until the first type II failure, then $Y_1 = \inf\{t \geq 0 : L(t) = 1\}$. Note that Y_1 is independent of $\{M(t), t \geq 0\}$. Thus, the survival distribution of the time until the first type II failure is given by

$$\begin{aligned} \bar{F}_p(t) &= P(Y_1 > t) = P(L(t) = 0) \\ &= \exp \left\{ - \int_0^t p(x)r(x) dx \right\} \end{aligned} \quad (2)$$

In order to develop the cost model, the following lemma from Sheu [40] is required.

Lemma 1 Let $\{M(t), t \geq 0\}$ be a nonhomogeneous Poisson process with intensity $\lambda(t)$, $t \geq 0$ and $\Lambda(t) = E[M(t)] = \int_0^t \lambda(x) dx$. Denote the successive arrival times by $S_1, S_2, \dots$. Assume that at time S_i ($i = 1, 2, \dots$) a cost of $\phi(C(S_i), c_i(S_i))$ is incurred. Suppose that $C(t)$ at age t is a random variable with finite mean $E[C(t)]$. If $\pi(t)$ is the total cost incurred over $[0, t]$, then

$$\begin{aligned} E[\pi(t)] &= E \left[\sum_{i=1}^{M(t)} \phi(C(S_i), c_i(S_i)) \right] \\ &= \int_0^t \vartheta(x) \lambda(x) dx \end{aligned} \quad (3)$$

where $\vartheta(t) = E_{M(t)}[E_{C(t)}[\phi(C(t), c_{M(t)+1}(t))]]$.

Model Development for Policy 1

For the maintenance policy 1, a system is replaced at age T or at the n th type I failure or at the first type II failure, whichever occurs first. Let c_2 denote the cost of replacement at the n th type I failure or at the first type II failure. Let c_1 denote the cost of replacement at age T . The cost of the minimal repair at age z is $\phi(C(z), c(z))$, where $C(z)$ is the age-dependent random part, $c(z)$ is the age-dependent deterministic part, and ϕ is a positive nondecreasing continuous function. Suppose that the random part $C(z)$ at age z has distribution $W_z(x)$, density function $w_z(x)$, and finite mean $E[C(z)]$. After a replacement the procedure is repeated. We assumed all failures are instantly detected and repaired.

Given that a type II failure does not occur in z , the conditional probability of k type I failures

during $[0, z]$ is

$$p_k(z) = P(M(z) = k | L(z) = 0) = P(M(z) = 0) \frac{e^{-\int_0^z q(x)r(x) dx} \left(\int_0^z q(x)r(x) dx \right)^k}{k!} \quad (4)$$

Let $\hat{Y}_1$ denote the time until the n th type I failure or at the first type II failure for our model with $T = \infty$. The survival distribution of $\hat{Y}_1$ is given by

$$\begin{aligned} \bar{G}(z) &= P(\hat{Y}_1 > z) \\ &= \sum_{k=0}^{n-1} P(L(z) = 0, M(z) = k) \\ &= \sum_{k=0}^{n-1} \bar{F}_p(z) p_k(z) \end{aligned} \quad (5)$$

For our model we have

$$U_1^* = \begin{cases} \hat{Y}_1 & \text{if } \hat{Y}_1 \leq T \\ T & \text{if } \hat{Y}_1 > T \end{cases} \quad (6)$$

Thus, the expected length of a replacement cycle is given by

$$\begin{aligned} E(U_1^*) &= \int_0^T z dG(z) + T \cdot \bar{G}(T) = \int_0^T \bar{G}(z) dz \\ &= \sum_{k=0}^{n-1} \int_0^T \bar{F}_p(z) p_k(z) dz \end{aligned} \quad (7)$$

On the other hand, the V_1^* can be expressed as follows:

$$\begin{aligned} V_1^* &= c_2 \cdot I_{[0, T]}(\hat{Y}_1) + c_1 \cdot I_{(T, \infty)}(\hat{Y}_1) \\ &+ \sum_{i=1}^{n-1} \phi(C(S_i), c(S_i)) \bar{F}_p(S_i) \cdot I_{[0, T]}(S_i) \end{aligned} \quad (8)$$

where S_i is the time of the i th minimal repair and

$$I_{[0, T]}(S_i) = \begin{cases} 1 & \text{if } S_i \in [0, T] \\ 0 & \text{otherwise} \end{cases} \quad (9)$$

Therefore, the expected total cost in a replacement cycle is

$$\begin{aligned} E(V_1^*) &= c_2 \left(1 - \sum_{i=0}^{n-1} \bar{F}_p(T) p_i(T) \right) \\ &+ c_1 \sum_{i=0}^{n-1} \bar{F}_p(T) p_i(T) + \sum_{i=1}^{n-1} \int_0^T \theta(z) \bar{F}_p(z) \\ &\times p_{i-1}(z) q(z) r(z) dz \end{aligned} \quad (10)$$

where $\theta(t) = E_{C(t)}[\phi(C(t), c(t))]$ is expectation with respect to the random variable $C(z)$. For the detailed derivation of equation (10), please refer to Sheu *et al.* [12].

Under policy 1, for the infinite-horizon case, we shall denote the right-hand side of equation (1) by $CR_1(n, T)$, the total expected long-run cost per unit time. And we want to obtain optimal n^* and optimal T^* which minimize $CR_1(n, T)$. Recall that

$$\begin{aligned} CR_1(n, T) &= \\ &= \frac{c_2 \left(1 - \sum_{i=0}^{n-1} \bar{F}_p(T) p_i(T) \right) + c_1 \sum_{i=0}^{n-1} \bar{F}_p(T) p_i(T) \\ &+ \sum_{i=0}^{n-2} \int_0^T \theta(z) \bar{F}_p(z) p_i(z) q(z) r(z) dz}{\sum_{i=0}^{n-1} \int_0^T \bar{F}_p(z) p_i(z) dz} \end{aligned} \quad (11)$$

Model Development for Policy 2

For the maintenance policy 2, if an operating system fails at age $z \leq t$, it is either replaced by a new system (type II failure) with probability $p(z)$ at a cost c_u , or it undergoes minimal repair (type I failure) with probability $q(z) = 1 - p(z)$. Otherwise, an operating system is replaced by a new system at a cost c_r when the first failure after t occurs, or is preventively replaced by a new system at a cost c_p when the total operating time reaches age T ($0 \leq t \leq T$), whichever occurs first. The cost of i th minimal repair at age z is $\phi(C(z), c_i(z))$, where $C(z)$ is the age-dependent random part, $c_i(z)$ is the deterministic part which depends on the age and the number of minimal repairs, and ϕ is a

4 Age-Dependent Minimal Repair and Maintenance

positive, nondecreasing, and continuous function. Suppose that the random part $C(z)$ at age z has distribution $W_z(x)$, density function $w_z(x)$, and finite mean $E[C(z)]$. After a replacement the procedure is repeated. We assumed all failures are instantly detected and repaired.

Let X_t denote the residual life of a system of age $t \geq 0$. Thus, X_0 means the life of a new system. Let $F_t(x)$ be the distribution function of X_t . If at time t a minimal repair is done, then

$$F_t(x) = \frac{F(t+x) - F(t)}{\bar{F}(t)} \quad (12)$$

and the corresponding survival function is

$$\bar{F}_t(x) = \frac{\bar{F}(t+x)}{\bar{F}(t)} \quad (13)$$

For our model we have

$$U_1^* = \begin{cases} Y_1, & \text{if } Y_1 \leq t \\ t + X_t, & \text{if } Y_1 > t, \quad 0 \leq X_t \leq T - t \\ T, & \text{if } Y_1 > t, T - t < X_t \end{cases} \quad (14)$$

and

$$V_1^* = \begin{cases} c_u + \sum_{i=1}^{M(Y_1)} \phi(C(S_i), c_i(S_i)), & \text{if } Y_1 \leq t \\ c_r + \sum_{i=1}^{M(t)} \phi(C(S_i), c_i(S_i)), & \text{if } Y_1 > t, \\ & 0 \leq X_t \leq T - t \\ c_p + \sum_{i=1}^{M(t)} \phi(C(S_i), c_i(S_i)), & \text{if } Y_1 > t, \\ & T - t < X_t \end{cases} \quad (15)$$

By equations (14) and (15), the expressions for $E(U_1^*)$ and $E(V_1^*)$ are given as follows:

$$E(U_1^*) = \int_0^t \bar{F}_p(x) dx + \bar{F}_p(t) \cdot U(t, T) \quad (16)$$

and

$$\begin{aligned} E(V_1^*) = & c_u \cdot F_p(t) + \int_0^t \vartheta(y) \bar{F}_p(y) \\ & \times q(y) r(y) dy + (c_r F_t(T - t) \\ & + c_p \bar{F}_t(T - t)) \bar{F}_p(t) \end{aligned} \quad (17)$$

where

$$\begin{aligned} U(t, T) &= \int_0^{T-t} \bar{F}_t(x) dx \\ &= \frac{\int_0^{T-t} \bar{F}(t+x) dx}{\bar{F}(t)} \end{aligned} \quad (18)$$

and

$$\vartheta(t) = E_{M(t)}[E_{C(t)}[\phi(C(t), c_{M(t)+1}(t))]] \quad (19)$$

For the detailed derivation of equations (16) and (17), please refer to Sheu *et al.* [41].

Under policy 2, for the infinite-horizon case, we shall denote the right-hand side of equation (1) by $CR_2(t, T)$, the total expected long-run cost per unit time, and we want to obtain an optimal pair (t^*, T^*) which minimizes $CR_2(t, T)$. Recall that

$$\begin{aligned} CR_2(t, T) = & \frac{c_u \cdot F_p(t) + \int_0^t \vartheta(y) \bar{F}_p(y) q(y) r(y) dy \\ & + (c_r F_t(T - t) + c_p \bar{F}_t(T - t)) \bar{F}_p(t)}{\int_0^t \bar{F}_p(y) dy + \bar{F}_p(t) U(t, T)} \end{aligned} \quad (20)$$

Optimization

Optimization Results for Policy 1

For Policy 1, we shall attempt to minimize $CR_1(n, T)$ with respect to (n, T) under the following assumptions:

- A1. The failure rate $r(z)$ is continuous, increasing and $r(z) \rightarrow \infty$ as $z \rightarrow \infty$.
- A2. The occurrence probability for type II failure, $p(z)$, is continuous and non-increasing.
- A3. The expected minimal repair cost at age z , $\theta(z)$, is continuous, nonincreasing, differentiable and $\theta(z)r(z) - \theta'(z)$ is continuous and increasing in z , where $\theta'(z) = (d\theta(z)/dz)$.

We see that the inequalities $CR_1(n+1, T) \geq CR_1(n, T)$ and $CR_1(n, T) < CR_1(n-1, T)$ are satisfied if and only if:

$$L(n, T) \geq c_1 \text{ and } L(n-1, T) < c_1 \quad (21)$$

where

$$L(n, T) = \begin{cases} \left\{ \frac{\sum_{i=0}^{n-1} \int_0^T \bar{F}_p(z) p_i(z) dz}{\int_0^T \bar{F}_p(z) p_n(z) dz} \left[\int_0^T (\theta(z)r(z) - \theta'(z)) \bar{F}_p(z) p_n(z) dz \right. \right. \\ \left. \left. + (\theta(T) + c_1 - c_2) \bar{F}_p(T) p_n(T) \right] \right\} \\ - \left\{ \sum_{i=0}^{n-2} \int_0^T \theta(z) \bar{F}_p(z) p_i(z) q(z) r(z) dz + (c_2 - c_1) \left(1 - \sum_{i=0}^{n-1} \bar{F}_p(T) p_i(T) \right) \right\}, \\ n = 1, 2, 3, \dots; \\ 0, \quad n = 0 \end{cases} \quad (22)$$

Differentiating $CR_1(n, T)$ in equation (11) with respect to T , we also see that $(dCR_1(n, T)/dT) = 0$ if and only if

$$Q(T, n) = c_1 \quad (23)$$

where

$$\begin{aligned} Q(T, n) = & r(T) \sum_{i=0}^{n-1} \int_0^T \bar{F}_p(z) p_i(z) dz \\ & \times \left[(\theta(T)q(T) + (c_2 - c_1)p(T)) \right. \\ & \left. - \frac{(\theta(T) + c_1 - c_2)p_{n-1}(T)q(T)}{\sum_{i=0}^{n-1} p_i(T)} \right] \\ & - \left[(c_2 - c_1) \left(1 - \sum_{i=0}^{n-1} \bar{F}_p(T) p_i(T) \right) \right. \\ & \left. + \sum_{i=0}^{n-2} \int_0^T \theta(z) \bar{F}_p(z) p_i(z) q(z) r(z) dz \right] \end{aligned} \quad (24)$$

Then, the main properties of the optimum pair (n^*, T^*) which minimizes $CR_1(n, T)$ are summarized below.

Theorem 1 *Under the assumptions A1, A2, and A3, we have the following results:*

1. If $c_2 \geq \theta(z) + c_1$ for $z \geq 0$, then the system is replaced at age T^* or at the first type II failure, whichever occurs first, and T^* satisfies $Q(T^*, \infty) = c_1$.
2. If $c_1 < c_2 < \theta(z) + c_1$ for $z \geq 0$, then the system is replaced at the n^* th type I failure or at age T^* or at the first type II failure, whichever occurs first, and n^* is a unique solution of $L(n^*, T) \geq c_1$ and $L(n^* - 1, T) < c_1$ and T^* satisfies $Q(T^*, n^*) = c_1$.
3. If $c_2 \leq c_1$, then there exists a finite and unique value of n^* that satisfies equation (21) for all $T > 0$, i.e., the system should be replaced at the n^* th type I failure or at age T or at the first type II failure, whichever occurs first.

For proofs of Theorem 1, see Sheu *et al.* [12, pp. 640–644].

Optimization Results for Policy 2

For Policy 2, we shall attempt to minimize $CR_2(t, T)$ with respect to (t, T) under the following assumptions:

B1. The failure rate $r(z)$ is continuous, increasing and $r(z) \rightarrow \infty$ as $z \rightarrow \infty$.

B2. The occurrence probability for type II failure, $p(z)$, and the expected minimal repair cost at age

$z, \vartheta(z)$, are continuous and nondecreasing functions, and $p(0) = 0$.

B3. $c_u \geq c_r > c_p > 0$, $(c_u - c_r)p(z) + \vartheta(z)q(z) > (c_r - c_p)q(z)$, and $c_r > \vartheta(z) > 0$ for $z \geq 0$.

The main results of the optimum pair (t^*, T^*) which minimizes $CR_2(t, T)$ are summarized below.

Theorem 2 Under the assumptions B1, B2, and B3, we have the following results:

1. If (t^*, T^*) is an optimal pair minimizing $CR_2(t, T)$, then $0 < t^* < T^* < \infty$.
2. The optimal pair (t^*, T^*) is uniquely determined, t^* is the solution of

$$r(T)U(t, T) + \bar{F}_t(T - t) - \frac{(c_u - c_r)p(t) + \vartheta(t)q(t)}{(c_r - c_p)q(t)} = 0 \quad (25)$$

and T^* is given by

$$T^* = r^{-1} \left(\frac{c_u - \frac{(c_u - c_r)\bar{F}_p(t^*)}{q(t^*)} - \vartheta(t^*)\bar{F}_p(t^*) + \int_0^{t^*} \vartheta(y)\bar{F}_p(y)q(y)r(y)dy}{(c_r - c_p) \int_0^{t^*} \bar{F}_p(y)dy} \right) \quad (26)$$

For proofs of Theorem 2, see Sheu *et al.* [41, pp. 342–346].

Remark 1 The assumption $c_u \geq c_r > c_p > 0$ is reasonable because

1. $c_r > c_p$ means that the corrective (unplanned) replacement cost is greater than that of the preventive (planned) replacement.
2. $c_u \geq c_r$ means that the replacement due to a type II failure before age t is more urgent (as well as unexpected) than if the first failure occurred after t .

Special Cases

Several well-known replacement policies are the special cases of policies 1 and 2.

Special Cases for Policy 1

- Case 1–1 ($n = \infty, p(z) = 0$, and $\phi(C(z), c(z)) = c$): this is the classical periodic replacement with minimal repair at failure. Barlow and Hunter [2] considered this case.
- Case 1–2 ($n = \infty, p(z) = 1$, and $\phi(C(z), c(z)) = 0$): this is the classical age replacement considered by Barlow and Hunter [2].
- Case 1–3 ($n = \infty, p(z) = 0$, and $\phi(C(z), c(z)) = c(z)$): this is the case considered by Boland [19].
- Case 1–4 ($n = \infty, p(z) = p, 0 < p < 1$, and $\phi(C(z), c(z)) = C$): this is the case considered by Cleroux *et al.* [7].
- Case 1–5 ($n = \infty$ and $\phi(C(z), c(z)) = C(z)$): this is the case considered by Berg *et al.* [10].
- Case 1–6 ($n = \infty, p(z) = 0$, and $\phi(C(z), c(z)) = c + c(z)$): this is the case considered by Tilquin and Cleroux [42].
- Case 1–7 ($n = \infty$ and $\phi(C(z), c(z)) = c$): this is the case considered by Beichelt [4].
- Case 1–8 ($T = \infty, p(z) = 0$, and $\phi(C(z), c(z)) = c_1$): Makabe and Morimura [28–30] considered this case. Park [34] also considered this case when $F(x)$ is a Weibull failure distribution.
- Case 1–9 ($T = \infty, p(z) = p$, and $\phi(C(z), c(z)) = c_1$): this is the case considered by Nakagawa [16].
- Case 1–10 ($T = \infty, p(z) = p$, and $\phi(C(z), c(z)) = C$): this is the case considered by Park [34].
- Case 1–11 ($p(z) = 0$ and $\phi(C(z), c(z)) = c_1$): this is the case considered by Morimura [31].
- Case 1–12 ($\phi(C(z), c(z)) = C(z) + c(z)$): here the cost of minimal repair is the age-dependent random part $C(z)$ plus the

deterministic part $c(z)$ and so $\theta(z) = E[C(z)] + c(z)$.

Special Cases for Policy 2

- Case 2-1 ($p(z) = 0$ and $\phi(C(z), c_i(z)) = c$): this is the policy considered by Tahara and Nishida [5].
- Case 2-2 ($t = 0$): this is the classical age replacement considered by Barlow and Hunter [2].
- Case 2-3 ($t = T$, $p(z) = 0$, and $\phi(C(z), c_i(z)) = c$): this is the policy 2 considered by Barlow and Hunter [2]. The problem reduces to the classical periodic replacement problem with minimal repair at failure.
- Case 2-4 ($t = T$, $p(z) = 0$, and $\phi(C(z), c_i(z)) = c(z)$): this is the case considered by Boland [19].
- Case 2-5 ($t = T$, $p(z) = 0$, and $\phi(C(z), c_i(z)) = c_i$): Boland and Proschan [18] investigated this case. In particular, they considered the cost structure $c_i = a + ic$.
- Case 2-6 ($t = T$, $p(z) = p$, $0 \leq p \leq 1$, and $\phi(C(z), c_i(z)) = C$): this is the case considered by Cleroux *et al.* [7].
- Case 2-7 ($t = T$ and $\phi(C(z), c_i(z)) = C(z)$): this is the case considered by Berg *et al.* [10].
- Case 2-8 ($t = T$ and $\phi(C(z), c_i(z)) = c_i(z)$): this is the case considered by Block *et al.* [11].
- Case 2-9 ($t = T$): this is the case considered by Sheu [43].
- Case 2-10 ($T = \infty$, $p(z) = 0$, and $\phi(C(z), c_i(z)) = c$): this is the case considered by Muth [6].
- Case 2-11 ($T = \infty$, $p(z) = p$, $q(z) = q = 1 - p$, $c_u = c_r$, and $\phi(C(z), c_i(z)) = C + cq$): this is the case considered by Bai and Yun [9].

Numerical Examples

Barlow and Proschan [14, p. 90] discussed an example of the classical age-replacement problem related to electron tubes used in airline communication and

give the solution when the underlying life distribution is truncated normal. Glasser [3] also give the solution in the cases of Gamma and Weibull distributions. Indeed, the very same case was also used by Cleroux *et al.* [7], Berg *et al.* [10], and Sheu [43] to exemplify the age-replacement policy and the block-replacement policy, respectively. In this example, we have $\mu = 9080$ and $\sigma = 3027$ for the underlying life distribution where the time unit is the hour.

In the numerical analysis here, we shall consider the system with Weibull distribution, which is one of the most common in reliability studies. The pdf of the Weibull distribution with shape parameter β and scale parameter α is given by

$$f(x) = \frac{\beta}{\alpha} \left(\frac{x}{\alpha}\right)^{\beta-1} e^{-\left(\frac{x}{\alpha}\right)^\beta}, \quad x > 0, \beta, \alpha > 0 \quad (27)$$

and the parameters of the distribution will be chosen to be $\beta = 2$ and $\alpha = 1012.2$.

Suppose that $\phi(C(x), c_i(x)) = C(x) + c(x)$. Here, we discuss a model in which, at failure, one replaces the system or repairs it depending on the random variable C . Let c_∞ be the constant. A replacement (type II failure) upon failure at age x takes place if $C > \delta(x)c_\infty$; if $C \leq \delta(x)c_\infty$, then one proceeds with a minimal repair (type I failure). The parameter $\delta(x)$ can be interpreted as a fraction of the constant c_∞ at age x , and $0 \leq \delta(x) \leq 1$. Here, we consider the following parametric form of the repair cost limit function $\delta(x) = \delta e^{-ax}$ with $0 \leq \delta \leq 1$ and $a \geq 0$, which is chosen for ease of computation. Suppose that the random variable C has a **normal distribution** $W(\cdot)$ and density function $w(\cdot)$ with mean μ_C and standard deviation σ_C .

If an operating system fails at age x , it is either replaced with a new system with probability

$$p(x) = 1 - \int_0^{\delta(x)c_\infty} w(z) dz \quad (28)$$

or it undergoes minimal repair with probability

$$q(x) = \int_0^{\delta(x)c_\infty} w(z) dz \quad (29)$$

The random part $C(x)$ of minimal repair cost at age x has density $l_x(z) = \frac{l(z)}{q(z)}$ for $0 \leq z \leq \delta(x)c_\infty$

8 Age-Dependent Minimal Repair and Maintenance

and

$$\begin{aligned}\vartheta(x) &= E[\phi(C(x), c(x))] = E[C(x) + c(x)] \\ &= \int_0^{\delta(x)c_\infty} z \cdot w_x(z) \, dz + c(x) \\ &= \frac{1}{q(x)} \int_0^{\delta(x)c_\infty} z \cdot w(z) \, dz + c(x) \quad (30)\end{aligned}$$

Numerical Results for Policy 1

In our computations, we consider the following three different cost cases:

Case 1a : $c_1 = 600, c_2 = 1200, c_\infty = 1000$,
 $\phi(C(x), c(x)) = 500, C \sim N(300, 60^2)$;

Case 1b : $c_1 = 1000, c_2 = 1200, c_\infty = 1000$,
 $\phi(C(x), c(x)) = C(x) + c(x), c(x) = 0.3x$,
 $C \sim N(300, 60^2)$;

Case 1c : $c_1 = 1200, c_2 = 1000, c_\infty = 1000$,
 $\phi(C(x), c(x)) = C(x) + c(x), c(x) = 0.3x$,
 $C \sim N(300, 60^2)$.

The parameters δ and a were varied to take the different values in order to see their effect on the optimal solution. When a is not equal to zero, the probability of minimal repairing is age dependent. The results are given in Tables 1, 2, and 3.

On the basis of the numerical results, we have the following remarks:

1. Some improvement can be made in the minimum cost per unit time if one allows for minimal repair at failure.

Table 1 Optimal replacement policy under cost case 1a

$q(y)$	δ	a	n^*	T^*	$CR_1(n^*, T^*)$
1.0	1	0	∞	1108.8	1.0822
0.9	0.377	0	∞	1108.8	1.1038
0.8	0.3505	0	∞	1108.6	1.1253
0.7	0.3315	0	∞	1108.4	1.1467
0.6	0.3125	0	∞	1108.1	1.1680
0.5	0.3	0	∞	1107.6	1.1892
0.3	0.2685	0	∞	1106.5	1.2313
0.1	0.223	0	∞	1105.0	1.2727
0.0	0	0	∞	1104.1	1.2932

2. From Table 1, the minimum cost per unit time will be reduced when the probability of minimal repairing is greater.
3. From Tables 2 and 3, the minimum cost per unit time will be reduced when the probability of minimal repairing is age dependent.
4. It can be seen that the present model of policy 1 is a generalization on previously known policies.

Numerical Results for Policy 2

In our computations, we consider the following two different cost cases:

Case 2a : $c_u = 1200, c_r = 1200, c_p = 1000,$

$c_\infty = 1100, \phi(C(x), c_i(x)) = C(x),$

$C \sim N(700, 200^2);$

Case 2b : $c_u = 1200, c_r = 1200, c_p = 1000,$

$c_\infty = 1100, \phi(C(x), c_i(x)) = C(x) + 0.1x,$

$C \sim N(700, 200^2).$

The parameters δ and a were varied to take the different values in order to see their influence on the optimal solution. When a is not equal to zero, the probability of minimal repair is age dependent. The results are given in Tables 4 and 5.

On the basis of the numerical results, we have the following remarks:

1. Some improvement can be made in the minimum cost per unit time if one allows for minimal repair at failure.
2. From Tables 4 and 5, the minimum cost per unit time will be reduced when the probability of minimal repairing is age dependent.
3. It can be seen that the present model of policy 2 is a generalization on previously known policies.

Conclusions

In this article, two extensions of age-replacement policies were presented and analyzed for a complex system that has two types of failures. Type I (minor) failure is removed by a minimal repair, whereas type II (catastrophic) failure is removed only by a replacement. The failure types are age dependent, and the repair costs are also generalized. Under policy 1 (i.e., the (n, T) policy), a system is replaced at the n th type I failure, or the first type II failure, or at age T , whichever occurs first. Under policy 2 (i.e., the (t, T) policy), if an operating system fails before age t , it is either replaced by a new system (type II failure), or it undergoes minimal repair (type I failure); otherwise, the system is correctively replaced by a new system when the first failure after t arrives, or preventively replaced by a new system when the total operating time reaches age T ($0 \leq t \leq T$), whichever occurs first. For operating the system in the long run, the expected cost per unit time was developed for the two maintenance policies, and the optimal pairs (n^*, T^*) and (t^*, T^*) that minimize the corresponding cost rate were determined, respectively. We have shown that under some mild conditions, the optimal solutions exist and they are unique. Various special cases were included and numerical examples were presented. Our results have extended many of the well-known results for the age-replacement policies.

However, we must point out the limitations of our models: Firstly, we have assumed that repairs are minimal. That means the repaired system is "as bad as old". In some practical situations, the repairs

are not minimal. Therefore, it is more reasonable to consider so-called imperfect repairs which bring the repaired system to a “better than the before-repair” state. Secondly, it is assumed that the repairs and replacements occur instantaneously. In fact, these actions may take time. Taking these realistic factors into consideration in the two maintenance policies can be one direction for future research. From the analysis of this study, we feel that our approach may not be feasible if more realistic factors are included in the model. Therefore, we need to adopt other modeling techniques to solve more general optimal replacement problems such as stochastic dynamic programming and simulation.

Burn-In and Maintenance Policies

Introduction

In this article we will use product, component, and system alternatively unless stated otherwise.

Burn-in is a widely used method in engineering. It can eliminate weak products from a population before they are released to customers. Thus it can greatly improve reliability performance of products. This method is particularly useful when the failure rate function of the products has a bathtub shape. By bathtub shape it is meant that the failure rate function strictly decreases at first until certain time point, say t_1 , then keeps as a constant until another time point, say t_2 , and it becomes strictly increasing afterward. The two time points t_1 and t_2 are called the *change points* of the failure rate function. The class of lifetime distributions with bathtub-shaped failure rate functions include many other lifetime classes such IFR (increasing failure rate), DFR (decreasing failure rate), and exponential distributions (constant failure rate) as special cases.

To perform a burn-in procedure, the products are operated for a certain time, say b , usually subject to more severe conditions encountered in field application. For more explanation about burn-in we refer to [1–3]. Insufficient burn-in time will not be able to improve the quality of a product significantly, and on the other hand excessive burn-in will damage the products' quality and will be very costly. A major concern of burn-in is to decide the optimal burn-in time, denoted as b^* , so that either the desired reliability measure of the burned-in products is optimized or the associated cost function is minimized.

Another important method applied in engineering is maintenance. Maintenance can raise the reliability of products, prolong mean residual life of products, reduce number of failure of products in field application, and increase availability of products. The most common maintenance actions include the following: (a) performing preventive repair/replacement; (b) allocating redundancies; and (c) conducting inspection (see [4]).

There are two basic repair models. One is complete repair, which repairs the failed product as good

as new. Sometimes the term *replacement* is an alternative to complete repair unless otherwise specified. The other is the so-called **minimal repair**, which repairs the failed product in such a way that the failure rate of the repaired product is exactly the same as the rate prior to the failure of the product.

Suppose that a system consists of several components, say $C_1, \dots, C_n$. One way to “bolster” this system is to provide spare components as redundancies of some of the components $C_i, 1 \leq i \leq n$. A major concern is which spare component should be used as **redundancy** of which $C_i, 1 \leq i \leq n$. In many cases the purpose of providing spare components is to achieve higher reliability subject to one or more constraints on expense, weight, volume, and so on. There are two different types of redundancy. One is standby (or cold) redundancy, which means that the redundant component will be operated at the failure of the original component. The other is active (or hot, or warm) redundancy, which means that both the redundant component and the original component are operated simultaneously and is thus equivalent to forming a parallel subsystem using the redundancy and the original component.

Inspection is necessary for detecting failure of a product if its failure is not self-announcing. Sometimes an age policy could be specified, which requires the product to be replaced at a specific age regardless of the status of the product at that time. It is certainly too costly to conduct too frequent inspections. However, on the contrary, too few inspections will significantly affect the availability of the product since the failed product will not be repaired for a long time. A trade-off between the frequency of inspection and the **system availability** must be made.

Optimal Burn-In Time

Let $F(x)$ be the distribution function of the lifetime X of a product. Assuming that the product exhibits a bathtub-shaped failure rate function, it has been shown that for any of the following reliability measures and cost functions the optimal burn-in time b^* never exceeds the first change point t_1 of the failure rate function.

Reliability Measures

Conditional Survival Probability. A product surviving the burn-in procedure with time b has a conditional survival function $\bar{F}_b(x) = \bar{F}(b+x)/\bar{F}(b)$,

where $\bar{F}(t) = 1 - F(t)$ is the survival function of X . Let $\tau > 0$ be a given mission time. Thus, the probability that this product operates for τ time units without failure is $\bar{F}_b(\tau)$. Often we may want to find out the optimal time b^* maximizing $\bar{F}_b(\tau)$ (see [5]).

Mean Number of Failures. Suppose that in field operation we use products surviving the same burn-in time b and that at failure, the failed product will be replaced by an independent and identically distributed (i.i.d.) one. Let $\tau > 0$ be a given mission time, and $N_b(\tau)$ be the number of failures in the interval $[0, \tau]$. Then the mean of $N_b(\tau)$ is given as $E(N_b(\tau)) = \sum_{i=1}^{\infty} F_b^{(i)}(\tau)$, where $F_b^{(i)}(x)$ is the i th convolution of $F_b(x)$. In practice we often want to find the optimal burn-in time b^* minimizing $E(N_b(\tau))$ (see [5]).

Mean Residual Life. After surviving the burn-in time b , the mean residual life of the product is given by $\mu(b) = E(X - b | X > b) = \int_b^{\infty} \bar{F}(t) / \bar{F}(b) dt$. It is natural that we want to find the optimal burn-in time b^* to maximize $\mu(b)$ (see [6]).

Cost Functions

During the burn-in procedure a product may fail before time b . Assume that the failed product will be replaced by a product with the same distribution and then the procedure will be continued. Let each replacement cost c_s . Further we assume that the cost of the burn-in per unit time is c_0 . It is shown in [7] that the mean cost incurred by this burn-in procedure is given by $k(b) = c_0 \int_0^b \bar{F}(t) / \bar{F}(b) dt + c_s F(b) / \bar{F}(b)$. Suppose that a product surviving the burn-in procedure has been put into field operation. If it fails before mission time τ , then a cost C will be incurred; and if it does not fail during the mission, then a gain G is obtained. Combining all the expenses and gain, it follows that the mean total cost function is given by $c_1(b) = k(b) + C(F(b + \tau) - F(b)) / \bar{F}(b) - G\bar{F}(b + \tau) / \bar{F}(b)$.

Suppose that the operation of a product surviving the burn-in procedure will yield a gain proportional to its mean life. Combining the burn-in cost and the gain in field operation, we have another total mean cost function expressed as $c_2(b) = k(b) - K \int_b^{\infty} \bar{F}(t) / \bar{F}(b) dt$, where K is the proportion constant.

Maintenance Models

Age-replacement policy is a common replacement model. Let $X_i, i \geq 1$ be the lifetimes of a sequence of products and $\tau > 0$ is a specified age. Suppose that at time zero a product is operated. This product will be replaced (or repaired) by another one at its failure or at age τ , whichever comes first. That is, $T_i = \min\{X_i, \tau\}$ expresses the operating time of the i th product. Usually the lifetimes $X_i, i \geq 1$ are i.i.d. Block *et al.* [8] extended this to the following general model by considering both complete repair and minimal repair. An operating product is completely replaced whenever it reached age τ . If it fails at age $x < \tau$, then it is either replaced by an i.i.d. one with probability $p(x)$ or undergoes minimal repair with probability $q(x) = 1 - p(x)$.

Block-replacement policy is another commonly used replacement model. Under this policy the product is replaced (or repaired) by another one at its failure or at scheduled (or planned) times $\tau, 2\tau, \dots$, where $\tau > 0$ is a predetermined number.

Cost Functions Resulting from Maintenance

In either the age-replacement policy or the block-replacement policy, both unscheduled (or unplanned) replacement at failures and scheduled (planned) replacement at age τ or at times $k\tau, k \geq 1$ are performed. In the literature there are thousands of papers that discussed various cost functions $C(\tau)$ associated with different combinations of preventive replacement policies and repair models. For more information we refer to [9, 10]. The optimal replacement policy, denoted as τ^* , is desired for minimizing the function $C(\tau)$. If the same τ is used for both age- and block-replacement policies and let $A(\tau)$ and $B(\tau)$ be the corresponding expected long-run cost per unit time respectively, then reference [11] gives an interesting result showing the connection between $A(\tau)$ and $B(\tau)$ by $B(\tau) = \int_{[0, \tau)} A(\tau - x) dU(x)$ where $U(x)$ is an appropriate renewal function. This equation means that $A(\tau)$ and $B(\tau)$ can be expressed in terms of each other.

Cost Resulting from Both Burn-In and Age Replacement

Suppose that an age-replacement policy τ is applied and i.i.d. products surviving burn-in time b will be

used for replacement. Combining the cost with both burn-in and age-replacement policy, we obtain the long-run average cost function $c(b, \tau) = c_1 F_b(\tau) + c_2 \bar{F}_b(\tau) + k(b) / \int_0^\tau \bar{F}_b(t) dt$, where $k(b)$ is the burn-in cost defined before, cost c_1 is suffered for each unscheduled replacement, and c_2 is a cost suffered from each scheduled replacement.

Cost Resulting from Both Burn-In and Block Replacement

We assume that at each failure the products will undergo a minimal repair and at each scheduled replacement a product surviving the burn-in time b will be used. Let c_m be the cost of each minimal repair, and c_r be the cost of a replacement. Combining the costs with both burn-in and age-replacement policy, we obtain the long-run average cost per unit time as a function of b and τ

$$c(b, \tau) = \frac{1}{\tau} \left(-c_s + \frac{c_s + c_0 \int_0^b \bar{F}(t) dt}{\bar{F}(b)} \right) + \frac{c_r + c_m \int_b^{b+\tau} r(t) dt}{\tau} \quad (1)$$

The problem of simultaneously searching the optimal burn-in time b^* and the optimal age/block-replacement policy τ^* minimizing the function $c(b, \tau)$ is considered in [12]. It is shown that $0 \leq b^* \leq t_1$ and $t_2 < b^* + \tau^* < \infty$ if the failure rate function of the products has a bathtub shape with change points $t_1 \leq t_2$.

System Availability without Inspection

Suppose that at time zero a system with lifetime U_1 is operated and will be repaired at its failure with time D_1 . Upon the completion of the repair the system is operated again with lifetime U_2 and will be repaired at its failure with time D_2 . The process will be continued in the same manner. At the failure of the system either complete or minimal repair is to be performed. The time period from the completion of one complete repair to the completion of the following complete repair is called a *cycle*. The point (or instantaneous) system availability at time t , denoted as $A(t)$, is defined as the probability

that the system is functioning at time t . The limit of $A(t)$ as $t \rightarrow \infty$, denoted as A , is defined as the stable (or steady) system availability if this limit exists. The average system availability on interval $[0, t]$, denoted as $\bar{A}(t)$, is the ratio of the total functioning time in $[0, t]$ to the length t of the interval $[0, t]$. The limit of $\bar{A}(t)$ as t goes to infinity, denoted as $\bar{A}$, is named the *long-run stable system availability* if the limit exists.

Mi [13, 14] generalized the above models and allows nonidentical (U_i, D_i) , $i \geq 1$. In particular, Mi [13] proved that under certain dominance conditions the steady system availability A exists and derived its expression.

Cha and Kim [15] and Iyer [16] considered the following model. Let $\{U_i, i \geq 1\}$ be the i.i.d. lifetimes of the systems. U_i has cumulative distribution function (CDF) $F(t)$, failure rate function $r(t)$, and mean μ . A new system starts working at time zero. It is assumed that in each cycle the probability of performing complete repair is given by $p(t)$, a predetermined function satisfying $0 < p(t) \leq 1$. Here, t is the age of the system in each cycle, i.e., prior to the start of the complete repair in each cycle the elapsed time from the initial instant of the cycle minus any accumulated minimal repair times within this cycle. Let $\{X_i, i \geq 1\}$ and $\{Y_i, i \geq 1\}$ be the i.i.d. minimal repair times and the i.i.d. complete repair times, respectively. Assume that $\{X_i, i \geq 1\}$ and $\{Y_i, i \geq 1\}$ are independent of each other as well as of the failure process. Denote the means of X_i and Y_i as v_m and v_c . It has been shown that under the above assumptions the long-run system availability is given as

$$\bar{A} = \frac{\int_0^\infty \bar{F}_p(t) dt}{\int_0^\infty \bar{F}_p(t) dt + v_m \int_0^\infty q(t) r(t) \bar{F}_p(t) dt + v_c} \quad (2)$$

where $q(t) = 1 - p(t)$ is the probability of performing minimal repair when the system has age t and $\bar{F}_p(t) = \exp\{\int_0^t p(u) r(u) du\}$.

System Availability with Inspection

Consider the case when the failure of a system can only be detected by inspection. The failed system found at inspection will be replaced by an i.i.d. one immediately and the times for implementing replacement are i.i.d. random variables Y_i , $i \geq 1$. The

4 Burn-In and Maintenance Policies

time needed for inspection is assumed negligible. The system will operate without any intervention if it is found to be functioning at an inspection. The inspection is characterized by a constant $\tau > 0$, and there is an age policy $\eta > 0$, where η is an integer or $\eta = \infty$, such that at time $\eta\tau$ the system is replaced regardless of the status of the system at that time.

Mi [17] showed that if $Y_i = 0, i \geq 1$, i.e. the time for implementing replacement is also negligible, then the long-run system availability is given by

$$\bar{A} = \frac{\int_0^{\eta\tau} \bar{F}(t) dt}{\tau \sum_{i=0}^{\eta-1} \bar{F}(i\tau)} \quad (3)$$

where F is the CDF of the lifetime of the system. Cui and Xie [18] assumed that $\eta = \infty$, Y_i has CDF G and showed that the long-run system availability is given by

$$\bar{A} = \frac{\int_0^{\infty} \bar{F}(t) dt}{\tau \sum_{i=0}^{\infty} \bar{F}(i\tau) + \int_0^{\infty} \bar{G}(t) dt} \quad (4)$$

Optimal Allocation of Components in Parallel-Series System

Let $P_i, 1 \leq i \leq k$ be the disjoint min path sets of a parallel-series system with sizes $n_1 \leq \dots \leq n_k$. Suppose that there are $n = \sum_{i=1}^k n_i$ independent components with reliabilities $p_i, 1 \leq i \leq k$. It is shown in [19] that the reliability of the system is maximized when the n_1 most reliable components are allotted to P_1 , the n_2 next most reliable components are allotted to P_2 , ..., and the n_k least reliable components are allotted to P_k .

Optimal Allocation of One Active Redundancy to k-out-of-n System

Suppose that $C, C_i, 1 \leq i \leq n$ are $n+1$ components with independent lifetimes $T, T_1 \leq^{\text{st}} \dots \leq^{\text{st}} T_n$. Let the lifetime of a k -out-of- n system composed of components $C_i, 1 \leq i \leq n$ be $\tau_k = \tau(T_1, \dots, T_i, T_{i+1}, \dots, T_n)$, and let $\tau_k^{(i)} = \tau(T_1, \dots, T_i \vee T,$

$T_{i+1}, \dots, T_n)$, where $T_i \vee T$ means that the component C is an active redundancy with component C_i .

It is shown in [20] that $\tau_k^{(1)} \leq^{\text{st}} \dots \leq^{\text{st}} \tau_k^{(n)}$. Mi [21] derived sufficient conditions under which one can find the optimal way of bolstering one component so that the reliability of the resulting k -out-of- n system is maximized.

Optimal Allocation of One Redundancy to Coherent System

Let $C, C_i, 1 \leq i \leq n$ be $n+1$ components with independent lifetimes $T, T_1 \leq^{\text{st}} \dots \leq^{\text{st}} T_n$. Denote the lifetime of coherent system (S, ϕ) consisting of components $C_i, 1 \leq i \leq n$ by $\tau_k = \tau(\mathbf{T})$ and let $\tau^{(i)} = \tau(T_i \vee T, \mathbf{T}^{(i)})$ where $\mathbf{T} = (T_1, \dots, T_n)$ and $\mathbf{T}^{(i)}$ is obtained by removing component T_i from $\mathbf{T}$. Using the concepts of “more critical” and “permutation equivalent” introduced in [22] the following results are shown in [23]: (a) If $i \stackrel{c}{=} j$ and $T_i \leq^{\text{st}} T_j$, then $\tau^{(j)} \leq^{\text{st}} \tau^{(i)}$; (b) if $i \stackrel{c}{>} j$ and $T_i \leq^{\text{st}} T_j$, then $\tau^{(j)} \leq^{\text{st}} \tau^{(i)}$; and (c) under the same conditions as in (b) it holds that $\tau^{(j)}(T_j + T, \mathbf{T}^{(j)}) \leq^{\text{st}} \tau^{(i)}(T_i + T, \mathbf{T}^{(i)})$.

Optimal Allocation of More Than One Redundancies to k-out-of-n System

Suppose that there are $n+r$ ($1 \leq r \leq n$) components available, of which r will be used for active redundancy. From the given $n+r$ components, r components are chosen to be used as active redundancies, and another r components receive active redundancies. Consider a k -out-of- n system consisting of the r bolstered and the other $n-r$ original components. Mi [24] studied the problem of which r components should be used for active redundancy, and where to allocate them to maximize the lifetime of the resulting k -out-of- n system. It is shown there that under the usual stochastic ordering $\leq^{\text{st}}$ the first r weakest components should be used for active redundancy and allocated in reverse order to the next r weakest components.

Warranty Cost Prediction Based on Warranty Data

Introduction

Generally, an extended warranty signals higher quality and reliability of a product and provides greater assurance and satisfaction to customers. However, extended warranties impose additional costs to the manufacturer. When a legitimate claim is made under warranty, the manufacturer incurs a cost to rectify the claim, which is known as *warranty cost* (see **Warranty Cost Analysis**). Warranty cost depends on the **warranty policy** and on the lifetime distribution (or reliability) of the product. Prediction of warranty cost means an assertion about the future warranty costs for a specified calendar period or about the amount of usage based on observed costs of claims or incorporating costs data from previous model years. For example, consider an automobile manufacturer that wants to predict the warranty costs up to an age of 5 years or a mileage of 50 000 km, whichever comes first, based on the initial claims data observed during the first year or first 10 000 km. The purposes of estimating and predicting warranty cost are to assess and improve product reliability by fitting the distribution of claims and to better manage the warranty program associated with the given warranty policy. Many approaches may be used to predict warranty costs depending on the warranty policy and on the nature of the available data and information [1]. In general, to predict future claims and costs, we need a statistical model (see **Warranty Modeling**) that depends on a vector of parameters, θ , to describe the claim population under the assumption that the failure modes and failure mechanisms of a product do not vary substantially during the prediction period.

Warranty Cost Prediction Based on Parametric CDF

Let X and Y denote the variables defining the warranty terms. For example, for a refrigerator under a one-dimensional (1D) policy, X would be the age, and for an automobile under two-dimensional (2D) policy, X would be the age and Y would be the mileage (see **Multiattribute Warranty Policies; Warranty Cost Analysis**). $F(x) = F(x; \theta)$

$= \Pr(X \leq x)$ and $F(x, y) = F(x, y; \theta) = \Pr(X \leq x, Y \leq y)$ are used to represent the cumulative distribution function (**cdf**) of X and the joint cdf of X and Y , respectively. Let the average manufacturing cost per unit be denoted by c_m and the average warranty cost (the cost incurred by the seller for servicing a claim) estimated from the data in warranty database be denoted by c_s . Under a 1D warranty with only first failure coverage [2], an estimate of the expected average cost per unit to the manufacturer for servicing a warranty within period $X = x_w$, denoted by $\hat{C}_1(x_w)$, is c_s times the proportion of units expected to fail within x_w ; that is, $\hat{C}_1(x_w) = c_s \hat{F}(x_w)$. Similarly, under a 2D warranty with only first failure coverage, the expected cost within the warranty coverage region ($X = x_w, Y = y_w$), denoted by $\hat{C}_2(x_w, y_w)$, is given by $\hat{C}_2(x_w, y_w) = c_s \hat{F}(x_w, y_w)$.

Under a 1D nonrenewing free replacement warranty [3, 4] for nonrepairable items, the expected warranty cost within period $X = x_w$ is c_m times the expected number of replacements in the interval $[0, x_w]$; that is, $\hat{C}_3(x_w) = c_m \hat{M}(x_w)$, where $M(x)$ is the *renewal function* (see **Renewal Theory**) associated with cdf $F(x)$. Similarly, under a 2D policy, the expected warranty cost within the warranty coverage region ($X = x_w, Y = y_w$) is $\hat{C}_4(x_w, y_w) = c_m \hat{M}(x_w, y_w)$, where $M(x, y)$ is a bivariate renewal function associated with $F(x, y)$ [5]. If the item is repairable (see **Nonparametric Methods for Analysis of Repair Data**), under a 1D warranty, the expected warranty cost is given by

$$\hat{C}_5(x_w) = c_s \int_0^{x_w} \mu(t) dt \quad (1)$$

where $\mu(t)$ is the failure *intensity function* for a *nonhomogeneous Poisson process* (see **Intensity Functions for Nonhomogeneous Poisson Processes**). The expected warranty cost for a 1D nonrenewing pro-rata rebate warranty with linear rebate function $q(x) = (1 - x/x_w)c_b$, $0 \leq x \leq x_w$ [3, 4] is given by

$$\hat{C}_6(x_w) = c_b \left[\hat{F}(x_w) - \frac{\hat{\mu}_{x_w}}{x_w} \right] \quad (2)$$

where c_b is the sale price (cost to buyer) per unit, and $\hat{\mu}_{x_w} (= \int_0^{x_w} x f(x) dx)$ is the partial expectation of X with **pdf** $f(x) = dF(x)/dx$. More detail on these methods and also on other policies are provided in Blischke and Murthy [3, 4, 6] and Murthy and Blischke [7]. The above methods require selection of parametric lifetime distributions that adequately

2 Warranty Cost Prediction Based on Warranty Data

represent the observed and often right censored warranty claims data (*see Warranty Claims and Costs: Statistical Analysis of; Warranty Modeling*). If the warranty database provides information on subsystem level and by failure mode, then the lifetime distributions and average costs can be estimated by subsystem and failure mode wise by their rectification action (repair or replace). These estimates can be used to predict the warranty cost for the overall product.

Menzefricke [8] derived a model to predict warranty costs and to estimate the mean and variance of total warranty cost to the manufacturer during a given period of time. Meeker and Escobar [9, Chapter 12] discussed methods for computing *predictions* and *prediction bounds* for the number of failures in a future time interval. Suppose a single group of units N is placed into service, and $r > 0$ units have failed in the interval $(0, x_c)$. If $F(x; \theta)$ describes the lifetime distribution, the point prediction for the number of additional failures, K , in a future interval (x_c, x_w) is $\hat{K} = (N - r)\hat{\rho}$, where $\hat{\rho} = \frac{\hat{F}(x_w; \theta) - \hat{F}(x_c; \theta)}{1 - \hat{F}(x_c; \theta)}$ is the conditional probability of failing in the interval (x_c, x_w) , given that a unit survived until x_c . The naive $100(1 - \alpha)\%$ upper prediction bound for K , $\tilde{K}(1 - \alpha)$, is computed as the smallest integer k such that $\text{BINCDF}(k; N - r, \hat{\rho}) \geq 1 - \alpha$, (BINCDF means binomial cumulative distribution function). Therefore, the predicted additional warranty cost until x_w would be $c_s \hat{K}$ with naive $100(1 - \alpha)\%$ upper prediction bound $c_s \tilde{K}(1 - \alpha)$. This method can be extended for predicting future claims and costs for more general situations in which multiple groups of units enter into service over a longer period of time (*see* [9]).

Age-Based Warranty Cost Prediction (Nonparametric Approach)

The *age-based* (or *age-specific*) evaluation of warranty cost has engendered considerable interest [10–14]. The age-based evaluation of warranty costs means **estimation** and prediction of warranty costs assuming that the expected number of claims per product at age t depends on t . Here we consider a month as the unit for age without loss of generality. If necessary, the unit “month” can be easily replaced by “week”, “day” and so on. Let S denotes the number of months of sale, M denotes the length of the observation period ($S \leq M$), and W denotes the length of the

warranty period. We assume that observed claims are stratified into k groups ($k = 1, 2, \dots, K$) based on the cost and define $c(k)$ as the average cost of a claim in group k , N_s as the number of products sold in month s , and $\{r_{st}(k), s = 1, 2, \dots, S; t = 1, 2, \dots, \min(M - s + 1, W); k = 1, 2, \dots, K\}$ as the reported number of claims of cost $c(k)$ at age t for those products sold in month s .

Let $\lambda_t(k)$ be the expected number of claims of cost $c(k)$ for a unit at age t , $t = 1, 2, \dots, \min(W, M)$. If claims occur randomly, the expected value of $r_{st}(k)$ is $N_s \lambda_t(k)$. Then the moment estimate of $\lambda_t(k)$ [12] can be expressed as

$$\hat{\lambda}_t(k) = \frac{\sum_{s=1}^{\min(S, M-t+1)} r_{st}(k)}{\sum_{s=1}^{\min(S, M-t+1)} N_s} = \frac{r_{\cdot t}(k)}{R_t} \quad (3)$$

where $R_t = \sum_{s=1}^{\min(S, M-t+1)} N_s$ is the total number of products sold up to month $\min(S, M - t + 1)$, and $r_{\cdot t}(k) = \sum_{s=1}^{\min(S, M-t+1)} r_{st}(k)$ is the total number of claims of cost $c(k)$ for units of age t reported up to month $\min(S, M - t + 1)$, for $t = 1, 2, \dots, \min(W, M)$, $k = 1, 2, \dots, K$. The estimate of cumulative total expected warranty cost per product up to age t is $\hat{C}_t = \sum_{k=1}^K c(k) \hat{\lambda}_t(k)$, where $\hat{\lambda}_t(k) = \sum_{i=1}^t \hat{\lambda}_i(k)$, $t = 1, \dots, \min(W, M)$.

To predict warranty cost, we define

$$Q_t(k) = \frac{1}{N} \sum_{i=1}^t \sum_{s=1}^{\min(S, M-t+1)} r_{si}(k) \quad (4)$$

as the average number of claims of cost $c(k)$ up to age t , per product sold, where $N = \sum_{s=1}^S N_s$, and

$$Q_t = \sum_{k=1}^K c(k) Q_t(k) \quad (5)$$

as the average total cost per product up to age t , $t = 1, 2, \dots, \min(W, M)$. Then $\hat{\lambda}_t(k)$ and $\hat{C}_t$ can be used to estimate $Q_t(k)$ and Q_t , respectively. Estimation of the variance and normal-approximation confidence limits for Q_t are explained in Kalbfleisch *et al.* [10] and Kalbfleisch and Lawless [11] for a more general case with reporting lag. This method provides an age-specific prediction of warranty costs for a finite population of units. If we wish to predict warranty costs for t greater than the length of claim-observed period,

M , $\lambda_t(k)$ must be estimated for $t > M$ using sources other than the current data. When the objective is to predict costs over calendar time, the predicted total cost of claims in month m , $\hat{Q}_m^*$, can be expressed by

$$\hat{Q}_m^* = \sum_{k=1}^K \sum_{s=\max(1, m-W+1)}^{\min(m, S)} c(k) N_s \hat{\lambda}_{m-s+1}(k), \quad m = 1, 2, \dots, M \quad (6)$$

For a future month m , the values of N_s for $s = S+1, \dots, m$, may also have to be estimated if the sales of the units are continued after month S , such that $m > S$.

Warranty Cost Prediction Based on Bayesian Approach

There is a limited literature on Bayesian approaches (see **Bayesian Reliability Analysis**) that addresses forecasting warranty claims and costs. Chen *et al.* [15] and [16] discussed methods for forecasting warranty claims and costs by using Markov mesh models which can be represented as a Bayesian dynamic linear models (DLM's). They proposed the DLM with leading indicators that used to incorporate data from previous model year and presented examples for forecasting the number of repairs and the cost of reporting a unit. Stephens and Crowder [17] also adopted the Bayesian approach with Markov chain Monte Carlo (MCMC) (see **Hierarchical Markov Chain Monte Carlo (MCMC) for Bayesian System Reliability**) sampling for predicting future warranty exposure.

Example

1. Suppose that the lifetime T of a product is distributed Weibull that is,

$$f(t; \eta, \beta) = \frac{\beta}{\eta} \left(\frac{t}{\eta}\right)^{\beta-1} \exp \left[-\left(\frac{t}{\eta}\right)^{\beta} \right], \quad t > 0 \quad (7)$$

with scale parameter $\eta = 5$ years and shape parameter $\beta = 1.5$. To model warranty claim data and estimate model parameters, see **Warranty Claims and Costs: Statistical Analysis of; Warranty Modeling; Warranty Cost Analysis**. Consider that for this product the manufacturing cost per unit, $c_m = \$300$, the sale price per unit, $c_b = \$500$, and the average cost incurred by the seller for servicing a claim, $c_s = \$50$.

- (a) Assuming only first failure coverage warranty, the predicted warranty cost per unit to the manufacturer for servicing a warranty for a warranty period of 2 year is $C_1(x_w = 2) = c_s \hat{F}(2) = 50 \times 0.2235 = \11.18 .
 - (b) Considering a nonrenewing free replacement warranty, the predicted warranty cost up to a warranty period of 2 year is $C_3(x_w = 2) = c_m \hat{M}(2) = 300 \times 0.2407 = \72.21 . For evaluation of renewal function, $M(\cdot)$, see Blischke and Murthy [3, 6].
 - (c) If the item is repairable (using **minimal repair**), under the Weibull nonhomogeneous Poisson process, the predicted warranty cost up to a warranty period of 2 year is $C_5(x_w = 2) = c_s \int_0^2 \mu(t) dt = c_s \times (2/\eta)^\beta = 50 \times 0.2530 = \12.65 .
 - (d) Assuming a nonrenewing pro-rata rebate warranty with linear rebate function $q(x) = (1 - x/x_w)c_b$, $0 \leq x < x_w$, from equation (2) the predicted warranty cost per unit to manufacturer for a warranty period of 2 year is $C_6(x_w = 2) = c_b \left[\hat{F}(2) - \frac{1}{2} \int_0^2 t f(t) dt \right] = 500 \times 0.0936 = \46.80 .
2. Pal and Murthy [5] showed that the warranty claim data of a motorcycle collected within the 2D warranty coverage region (age $X = 180$ days, usage $Y = 8000$ km) follows Gumbel's bivariate exponential model as

$$F(x, y) = 1 - e^{-\left(\frac{x}{\theta_x}\right)} - e^{-\left(\frac{y}{\theta_y}\right)} + e^{-\left\{\left(\frac{x}{\theta_x}\right)^\delta + \left(\frac{y}{\theta_y}\right)^\delta\right\}^{1/\delta}}, \quad x, y \geq 0 \quad (8)$$

with the estimates of the parameters $\hat{\theta}_x = 357.0$, $\hat{\theta}_y = 10077.5$ and $\hat{\delta} = 3.15$. The average warranty cost per claim for this product is $c_s = 428.4$ rupees. Therefore, the predicted warranty cost for the extended warranty coverage region ($X = x_w = 365$ days, $Y = y_w = 12000$ km) is $\hat{C}_2(365, 12000) = c_s \hat{F}(365, 12000) = 428.4 \times 0.586 = 251.04$ rupees.

3. Suppose that a product has a 6-month warranty period and that $N_s = 1000$ units are sold on each month $s = 1, 2, \dots, S$. Assume that claims are observed during 6-month period ($S = 6$) and

classified into three groups ($K = 3$) based on warranty cost, and the estimates of the expected number of claims $\hat{\lambda}_t(k)$ defined by equation (3) for three groups are $\{\hat{\lambda}_t(1), \hat{\lambda}_t(2), \hat{\lambda}_t(3)\} = \{(0.004, 0.006, 0.008, 0.007, 0.013, 0.018), (0.004, 0.008, 0.005, 0.006, 0.009, 0.015), (0.003, 0.009, 0.008, 0.009, 0.005, 0.007)\}$. For simplicity of illustration, assume that on each month the same amount 1000 units are continued to sale up to 12 month. If the average cost of a claim in groups one, two and three are $c(1) = \$10.0$, $c(2) = \$20.0$ and $c(3) = \$30.0$, respectively, then using equation (6) the predicted cost at month 12 ($m = 12$) is $\hat{Q}_{12}^* = \sum_{k=1}^3 \sum_{s=7}^{12} c(k) N_s \hat{\lambda}_{12-s+1}(k) = \2730 .

Summary

This article reviewed some methods for predicting warranty cost during a given future value(s) of the variable(s) defining the warranty terms. It modeled the predicted cost as a function of the lifetime distribution of the product and the average cost per claim based on observed costs of previous claims or incorporating costs data from previous model years.

Warranty Servicing

Introduction

When a warranty is given with the sale of a product, the manufacturer has to service all claims made by the customers. Warranty costs (*see* **Warranty Cost Analysis; Warranty Cost Prediction Based on Warranty Data**) are the additional expenses that the manufacturer incurs in servicing these **warranty claims**. Models to estimate warranty costs for many different types of warranties can be found in Blischke and Murthy [1, 2], and a review of the literature on **warranty cost** modeling from 1990 to 2000 is given in Murthy and Djamaludin [3].

Warranty costs can be reduced by performing effective warranty servicing. To do this, the manufacturer needs to address various issues at both the strategic and operational levels. In this article, we develop a framework that links all the issues involved in warranty servicing and we review the models that have been developed to make optimal servicing decisions. The outline of the article is as follows. The Section titled “Framework for Warranty Servicing” deals with the servicing framework and, in the section titled “Servicing Strategies”, we review servicing strategies that involve repair *versus* replace decisions for the manufacturer at product failures. Finally, we state our conclusions.

Framework for Warranty Servicing

The warranty servicing process is shown in Figure 1.

Warranty Claims

The number of warranty claims (*see* **Warranty Claims and Costs: Statistical Analysis of**) that a manufacturer has to service is a function of (a) the terms of the **warranty policy**, (b) the number of items sold, and (c) the number of product failures. The number of failures depends on the inherent product reliability (influenced by the design and production decisions taken by the manufacturer) and on the usage mode and environment (influenced by the consumer).

Warranty Policies. The two most common warranty policies (*see* **Multiattribute Warranty Policies;**

Warranty Modeling) for consumer durables and industrial or commercial products are the prorata warranty (PRW) and the free replacement warranty (FRW). At each product failure, the manufacturer refunds a fraction of the purchase price to the customer under a PRW and repairs or replaces the item free of charge under a FRW. Both of these warranties may also be characterized as either renewing or nonrenewing. In the renewing case, all replaced or repaired items are covered by a warranty identical to that of the original purchased product. In the nonrenewing case, the coverage for a replaced or repaired item is only for the remainder of the original warranty period. Another important characteristic of a warranty is its dimensionality. In a one-dimensional warranty, the product is covered for a certain time interval and, in the two-dimensional case, the warranty coverage is characterized by a two-dimensional planar region with one axis representing time and the other axis representing usage. A taxonomy for warranty policies is proposed by Blischke and Murthy [2].

Product Reliability. A product is a complex item that fails due to the failure of one or more of its many components. The product can be restored to an operational state by replacing or repairing all the failed components (*see* **Replacement Strategies; Imperfect Repair; General Minimal Repair Models; Repairable Systems Reliability**) and the time taken to do this is usually small relative to the time between failures. The manufacturer needs to be able to estimate the number of product and component failures for repair-facility planning.

At the product level, failure occurrences can be modeled by a stochastic point process with a given **intensity function**. In order to model component level failure, a renewal process (*see* **Markov Renewal Processes in Reliability Modeling**) is used in the nonrepairable case and a point process is required for a repairable component. Details of these modeling techniques can be found in Blischke and Murthy [1, 2].

Product Usage. Product usage intensity (such as number of miles traveled per year by a car, number of times a washing machine is used per week – *see* **Warranty: Usage and Wear Process for**) and operating environment vary across the customer population. This variation changes the rate at which products fail and the number of warranty claims that

Figure 1 Warranty servicing process

need to be serviced. Cost models for products sold with a FRW under varying usage intensity are studied by Kim *et al.* [4].

Product Sales and Warranty Claims. Let L denote the length of the product life cycle, which is the time period from when the product is first introduced into the market until the instant it is replaced in the market by a new and better product. Let W denote the length of the warranty period. If the product is sold with non-renewing FRW policy, then warranty claims occur at random points over the interval starting at time zero when the product is first introduced and ending at time $(L + W)$ when the warranty ceases for the last items sold.

If the intensity function (given by the rate of occurrence of failures (ROCOF)) for product failures is known then the expected warranty claims rate (expected number of claims per unit time) over the interval $[0, L + W)$ can be determined from this ROCOF and the sales rate (sales per unit time), see Blischke and Murthy [1, 2]. Typical plots of the sales rate and the corresponding expected claims rate are given in Figure 2. Both curves show an initial increase, reach a maximum level, and then decrease

to zero with the expected claims rate always lagging the sales rate.

Warranty Servicing

The strategic issues in warranty servicing that the manufacturer needs to consider are (a) the number of service centers and their location, (b) the capacity and staffing for each service center (to ensure prompt response times for customer satisfaction), and (c) whether to own these centers or to outsource the servicing to an independent agent.

The tactical and operational issues are (a) the transportation of the material needed for warranty

Figure 2 Sales rate and expected warranty claims

servicing, (b) management of spare parts inventory, (c) job scheduling, and (d) optimal repair/replace decisions for failed items.

Strategic Issues. The location of service centers (for carrying out repairs) and warehouses (for stocking spares needed) depend on the geographical distribution of customers who have bought the product, the type of product, and its reliability characteristics.

Sometimes, it is necessary to carry out on-site evaluation and repair of a failed product (such as a lift in a building). Otherwise, the failed item is taken to either the retailer (in the case of most consumer durables) or directly to a designated service center. Depending on the complexity of the product, it might also have to be moved between service centers operating at different levels to have its repair completed. The problem of deciding where an item should be repaired in a multiechelon repair facility has received some attention in the logistics literature and is known as *level of repair analysis* (LORA). Alfredsson [5] deals with decisions with regard to LORA and the spare parts and test equipment needed to support a system. Barros and Riley [6] deal with optimization of the LORA.

Models to determine the number of levels, the location of the service centers and their capacities must take into account the transportation time and cost for moving failed and repaired items between service centers, and the cost of operating the service centers (equipment and skilled persons needed at each center).

The manufacturer might also need a network of warehouses with a multiechelon structure involving one or more levels. Two key issues are the location of the warehouses and the capacity of each warehouse, defined through the quantities of different components that need to be stocked. This problem has received some attention in the logistics literature. However, the models need to be modified to take into account the location of the service centers and the reliability characteristics of the product.

The optimal warehouse location must take into account the transportation time and cost for moving parts between warehouses (in the case of a multiechelon structure) and from warehouses to service centers, the cost of operating the warehouses, and the capacity of each warehouse based on the demand for spares from the various service centers that are serviced by the warehouse.

The service center capacity requirement is determined by the service demand, which depends on the geographical distribution of sales and on product reliability. In solving the location problem, the issues of coverage (so that all the customers are covered), distance that a failed item must travel, and distance that a repairman has to travel in case of a field visit or that a customer has to travel to bring a failed item to a service center or collection point have to be addressed. Given the coverage, the model based on sales over a region can be used to determine the demand and the service center capacity.

The management of inventory levels for service support logistics deals with ordering policies. There is a trade-off between the cost associated with, and the benefits derived from, having an inventory, and several ordering strategies have been proposed and studied. These include the reorder point control, fixed interval control, and the min-max control (see Nahmias [7] and Sherbrooke [8]). The total demand for spares (of a component) at a warehouse over the product life cycle can be modeled using the techniques described in the section titled "Product Sales and Warranty Claims".

If the manufacturer decides to outsource the warranty servicing to independent agents then properly drafted contracts are essential. The interests of the two parties (manufacturer and agent) are different and this raises several new issues that are highlighted in the following example.

Contract A: The manufacturer pays a lump sum to the agent and in return the agent has to service all claims during the warranty period at no additional cost to the manufacturer.

Contract B: The service agent charges the manufacturer for each warranty service.

The new and relevant issues here include:

Informational asymmetry

The manufacturer has better knowledge of product reliability compared with the agent and similarly the agent has better information regarding field failures than the manufacturer. This asymmetry can lead to each party deciding on actions that are optimal from their own individual perspective but overall suboptimal.

Moral hazard

This situation arises when the agent shirks in the effort expended (under Contract A) or carries out

4 Warranty Servicing

overservicing (under Contract B) and the manufacturer is unable to observe the service agent's effort. In the former case, this can lead to customer dissatisfaction which can affect the manufacturer's reputation and sales.

Monitoring

The manufacturer can obtain new information by monitoring the agent's actions. Such information will allow the manufacturer to assess the warranty servicing carried out by the agent but this results in additional effort and cost to the manufacturer.

Adverse selection

This issue arises when the manufacturer has to choose one or more service agents to carry out the warranty servicing from a pool of service agents. The service agents can misrepresent their ability and competencies and the manufacturer is not able to assess them prior to the signing of the contract. This can lead to the selection of inappropriate agents to service warranty.

Incentives

The manufacturer can provide proper incentives to the service agents so that the actions of the agents are in the best interests of the manufacturer and avoid the need for monitoring. A proper contract provides the right incentives for the service agent to provide the optimal effort.

Agency cost

The structuring, administering, and enforcing of contracts result in a cost that is referred to as the *agency cost*.

Risks

The manufacturer and the service agents have partly differing goals and risk preferences and both of these have an impact on their individual actions.

Agency theory (see Eisenhardt [9] and van Ackere [10]) can provide the framework needed to deal with the above issues, but it has yet to be applied to warranty servicing contracts.

Operational Issues. The key issues in spare parts inventory management are, making decisions about the components that should be carried as spare parts, the inventory levels of the spares, and the timing and amount of spares that should be ordered. To do this, information is required about the expected

number of component failures over time and this, in turn, depends on the level of sales over time and on **component reliability**.

Most models dealing with spare part inventories assume very simple forms for the depletion of inventory. In the warranty-servicing context, the depletion of the inventory of a particular component occurs in an uncertain manner that depends on the sales rate over the region serviced by the servicing center and the reliability of the product. Optimal decisions with regard to inventory levels and ordering policies need to take this into account.

In warranty servicing logistics, the three kinds of material that needs to be transported are (a) failed units from a lower level to a higher level in the case of a multiechelon service structure, (b) repaired items from service centers to customers or pickup points where customers can collect them, and (c) spares to and from warehouses. In each case, the amounts to be moved are random variables related to sales and product reliability.

The material transportation can be carried out either by the manufacturer or by an independent agent. In the latter case, a contract between the manufacturer and the agent must take into account the transportation cost, the frequency of transportation, upper limits on quantities to be transported, time limits, penalties for delays in delivery, breaches of contract, and so on. The Agency theory issues discussed in the section titled "Strategic Issues" are also relevant here and different contract options may be evaluated using this framework.

Products may be differentiated according to whether they are brought to a service center when they fail or whether a repairman goes out to rectify the failure. In the former case, the scheduling of repair jobs is an important issue that not only has an impact on the overall cost of providing the service but also on customer satisfaction. Job scheduling has been extensively studied [11–13]. The latter case results in the "traveling repairman problem", and a number of solutions have been proposed [14–16] to schedule jobs to reduce traveling time. If the warranty on the product includes penalties for servicing delays, then the scheduling also needs to take this into account.

The remaining operational issue in warranty servicing on repair *versus* replace decisions is discussed in the next section.

Servicing Strategies

Whenever a repairable product fails under warranty, the manufacturer has the option of either repairing the failed item or replacing it with a new one. The first option costs less than the second but the repaired item has a greater probability of failing during the remainder of the warranty period. It is therefore important for the manufacturer to choose an appropriate servicing strategy in order to minimize the expected cost of servicing the warranty for each product sold (*see Warranty Cost Analysis*).

Servicing strategies for products sold with one-dimensional warranties have received considerable attention. In a cost-repair limit strategy, an estimate of the cost to repair a failed product is made and by comparing it with some specified limit, the failed item is either repaired or replaced by a new one. Optimal repair limit strategies are discussed in Blischke and Murthy [1] and Zuo *et al.* [17].

In most of the remaining models in the literature, average repair costs are used to make the repair *versus* replace decisions. Biedenweg [18] and Nguyen and Murthy [19, 20] assume that repaired items have independent and identically distributed lifetimes different from that of a new item and consider strategies where the warranty period is divided into distinct intervals for repair and replacement. Nguyen [21] introduces the first servicing model with minimal repair (*see* Barlow and Hunter [22] and **General Minimal Repair Models**), the warranty period split into a replacement interval followed by a repair interval. The length of the first interval is selected optimally to minimize the expected warranty cost.

Jack and Van der Duyn Schouten [23] show that this strategy is suboptimal and that the optimal servicing strategy is in fact characterized by three distinct intervals – $[0, x]$, $[x, y]$ and $(y, W]$ where W is the warranty period. The optimal strategy is to carry out minimal repairs in the first and last intervals and to use either minimal repair or replacement by new in the middle interval depending on the age of the item at failure. (Refer to Jiang *et al.* [24] for the optimality of this strategy.) This strategy is difficult to implement, so Jack and Murthy [25] proposed a near optimal strategy involving the same three intervals but with only the first failure in the middle interval resulting in a replacement and all other failures being minimally repaired. (Refer to Sheu and Yu [26] for the case with random minimal repair cost.)

When the cost of replacement is high compared to the cost of a minimal repair then strategies involving replacement are not appropriate. In this case, **imperfect repair** strategies (where the failure characteristics of the repaired item are better than those after minimal repair but are not the same as a new item) can be used. The advantage of using imperfect repair (*see Imperfect Repair*) is that the degree of improvement in the reliability after repair is a decision variable under the control of the manufacturer. The literature on imperfect repair has focused mainly on its use in the context of preventive and corrective maintenance of unreliable systems. See, for example, Wang [27], Li and Shaked [28], Doyen and Gaudoin [29], Zequeira and Berenguer [30], Sheu *et al.* [31], and Tang and Lam [32]. Chukova *et al.* [33] study the successive operating times of a product under different types of imperfect repair.

Yun *et al.* [34] consider two servicing strategies (servicing strategies 1 and 2 respectively) involving minimal and imperfect repairs. In both strategies a failed product is subjected to at most one imperfect repair over the warranty period.

In strategy 1, all item failures occurring in the interval $[0, x)$ are minimally repaired. The first failure in the interval $[x, y]$ is rectified by imperfect repair with the proportional reduction factor in the hazard rate $\delta(t)$ depending on the age t at failure. The cost of an imperfect repair is an increasing function of the item age and the proportional reduction in the hazard rate. All subsequent failures in the interval $[x, y]$ are minimally repaired, as are those that occur in the remaining interval $(y, W]$. This strategy is characterized by the set $\{x, y, \Delta(x, y)\}$ consisting of the two parameters x and y , and the function $\Delta(x, y) \equiv \{\delta(t), x \leq t \leq y\}$. These are the decision variables that need to be selected optimally to minimize the expected warranty servicing cost $J(x, y, \Delta(x, y))$. Strategy 1 is similar to that proposed by Jack and Murthy [25] except that an imperfect repair is performed instead of a replacement in the interval $[x, y]$.

In strategy 2, the proportional reduction in the hazard rate does not change with time over the interval $[x, y]$. It is a parameter (δ) to be selected optimally. In this case, the strategy is characterized by the three parameters x , y , and δ , and these are to be selected optimally to minimize the expected warranty servicing cost $J(x, y, \delta)$.

Servicing strategies for products sold with two-dimensional warranties have also received some

attention. Iskandar and Murthy [35] examined two strategies similar to those in Nguyen and Murthy [19, 20] but with minimal repair. Iskandar *et al.* [36] discussed a servicing strategy similar to that given in Jack and Murthy [25]. (Refer to Chukova and Johnston [37] for the case without a restriction assumed by Iskandar *et al.* [36].)

Conclusions

There are still many aspects of warranty servicing that need further investigation. These include (a) the design of incentive contracts based on Agency theory when the servicing is outsourced, (b) models to study the various operational and strategic issues involved in warranty logistics, and (c) new servicing strategy models for products sold with two-dimensional warranties.

Sampling Inspection of Products

Statistical Product Inspection in Industrial Quality Control

Industrial **quality control** can be systematized in different ways. A popular systematization is arranged by *subject matter*: *design control*, **process control**, *product control*, where the term “product” is used in a broad sense meaning any completed identifiable entity like materials, parts, products, services, software, or data, see the definition by ISO 9000, [1]. In manufacturing, product control is often subdivided into *incoming material control (input control)* and *finished product control (output control)*. Product control is situated at the interface of two parties: a *supplier* or *vendor* or *producer* as the party providing product and a *customer* or *consumer* as the party receiving product. Supplier and customer may be part of the same organization (internal supplier) or of different organizations (external supplier).

Another systematization of quality control follows the *control objectives*: *preventive* control is distinguished from *monitoring* or *inspection* of results. Prevention is characterized by the interest of avoiding quality problems by creating an environment favorable for quality. Monitoring collects information on the results of routine business for assessment purposes. The assessment leads to a decision between two alternatives *accept* or *reject*. In a reasonable industrial environment, acceptance is the regular case and means *continue with routine business* whereas rejection calls for some extraordinary *intervention*.

Design control is essentially preventive in nature. Process and product control have both preventive and inspection aspects. Inspection in product control occurs as *receiving inspection* of incoming material, parts, products, or as *final inspection* of outgoing finished product. The inspection serves as a basis for an assessment of material or product with a subsequent decision on the alternatives accept or reject.

Inspection and decision in product control can take two directions. A *type A* procedure is directed toward a single assembled *lot* of product. A *type B* procedure is directed toward the *process* of manufacturing, transport, storage which provides the product. The

distinction between type A and type B procedures is adopted by ISO 2859-2 [2], for instance.

A type A procedure is concerned with the decision alternative *acceptance of the lot* and *rejection of the lot*, with the following interpretations. *Acceptance of the lot* (routine case): (a) final inspection: forwarding the lot to another department for processing, shipping the lot to a customer. (b) receiving inspection: accept the lot from the shipper for reselling or processing. *Rejection of the lot* (intervention): 100% rectification of the lot, i.e., sorting out and repairing or replacing improper items; return the lot to the manufacturing department or external supplier; sell product at a reduced price; scrap product.

A *type B* procedure is a combined lot and process assessment procedure. The decisions *acceptance* and *rejection* refer both to the individual lot, in the way exemplified for type A procedures, and to the process behind the lot with the following interpretations. *Acceptance*: continue the process of manufacture or delivery in a routine manner without intervention. *Rejection*: intervene into the process, e.g., send the inspection result as an alert to the manufacturing department, launch an inspection of the manufacturing process to detect assignable causes of quality variation, complain to the product provider requiring quality control interventions.

Deming [3] defines statistical quality control (SQC) as the “application of statistical principles and techniques in all stages of design, production, maintenance, and service, directed toward the economic satisfaction of demand”. Statistical methods are used for design, process, product control, both with preventive and monitoring (inspective) interest. Inspective SQC is based on *sampling*. The two most popular sampling based procedures are the **control chart** in **statistical process control** (SPC) and **acceptance sampling** (*statistical product inspection, SPI*) in product control. In SPI, the decision on acceptance or rejection of incoming or outgoing product is based on a sample taken from a lot, or from the process behind the lots.

The subsequent sections analyze the basics of SPI from a historical, practical, and methodological point of view.

Historical Background of Statistical Product Inspection

In the Taylorist production environments growing in the first decades of the twentieth century manufacturing was split up into a number of simple consecutive steps. Quality control was identified with inspection of parts at the end of each production step, terminating in a final inspection of finished product. After World War I, expanding mass production made 100% inspection infeasible and involved sampling techniques. The systematic development of statistical lot inspection schemes started in the 1920s. Early contributions are due to Becker [4] and to a group integrating H.F. Dodge and W.A. Shewhart in the “inspection engineering” department at Bell Telephone Laboratories founded in 1925, see the documentation by Dodge [5, 6]. SPI schemes prospered as the main branch of SQC in theoretical development and in industrial practice until the 1950s. Most popular exponents are the *Dodge–Romig Tables* and the *Military Standard* series, in particular MIL-STD-105 and MIL-STD-414, which originated in inspection schemes of the U.S. armament industry during World War II. At that time, lot inspection had a direct quality regulating purpose, as expressed by Dodge [7]: “The purpose of the inspection is to determine the acceptability of individual lots submitted for inspection, i.e., sorting good lots from bad.”

Industry faced new challenges in the decades after World War II: market saturation, tightening quality demands, legal obligations, consumer and environmental protection, globalization, increasing cost of material and labor, technological progress, increasing complexity of products. Quality control had to rearrange priorities: from product control to design and process control, from inspective to preventive methods. The traditional emphasis on **product inspection** was severely criticized. Deming [8] formulates number 3 of his 14 principles for transformation of western management: “Cease dependence on inspection to achieve quality. Eliminate the need for inspection on a mass basis by building quality into the product in the first place.” The new orientation of industry changed SQC. The field of statistics in quality control was considerably enlarged, exceeding the classical SQC core disciplines SPC and SPI. Statistics can be useful at any of the stages of the quality loop. SPI schemes lost reputation and were even attacked as completely obsolete, see [9] or [8].

However, inspection still has a place in modern product quality control. ISO 9004 [10], mentions inspection as a tool of product control under the issues *receiving inspection planning*, *verification of incoming material and parts*, *completed product verification*. The latter issue explicitly mentions 100% inspection (screening) and sampling inspection of lots. SPI can play a reasonable role if it is designed not as a quality regulating but as an adjunct tool in a product control system based on prevention and on cooperative supplier–customer relations. The specific challenges for statistical lot inspection in modern industrial environments are discussed in more detail by **Acceptance Sampling in Modern Industrial Environments**.

Quality Modeling in Product Inspection

A clear idea of item quality, lot quality, and process quality is indispensable for reasonable SPI.

Consider discrete items (units) $i = 1, 2, \dots$. Each item i is ascribed a characteristic X_i which is influenced by random events during production, transport, and storage. The quality of item i is supposed to be determined exclusively by X_i , the *quality indicator of item i* . A lot is a finite set of items (units) $1, \dots, N$ of finished product considered at a fixed time. Hence the quality of a given lot is fixed and depends exclusively on the quality of the items in the lot. It is quantified by the *lot quality indicator* Q as a function $Q = Q(X_1, \dots, X_N)$ of the quality indicators of the items in the lot. The choice of the lot quality indicator reflects the economic appraisal of the lot: the economic value of the lot should depend on the quality $X_1, \dots, X_N$ of the items in the lot only through the lot quality indicator Q . The most important lot quality indicator is the *lot mean* $Q = 1/N \sum_{i=1}^N X_i = \bar{X}_{\text{lot}}$.

Each lot of items $1, \dots, N$ is assembled from a process of manufacturing, handling, transport, and so on. The process is the original source of variation in the item quality indicators X_i and in the lot quality indicator $Q(X_1, \dots, X_N)$. Hence it is important to conceive an idea of process quality. From a stochastic point of view, process quality is determined by a parameter of the probability distribution of the random item quality indicator X_i . In many cases, the suitable process quality indicator is the expectation $\theta_i = E[X_i]$ of the item quality indicators resulting

from the process, i.e., the average process level. For specific applications, other distribution parameters may be of interest, as for instance **quantiles** in **reliability analysis**.

The following quality models are the most important instances of the above framework in acceptance sampling.

Conforming–nonconforming quality model

Item quality indicators: binary variables $X_i \in \{0, 1\}$ where $X_i = 0$, if item i is conforming, $X_i = 1$, if item i is nonconforming. Lot quality indicator: lot proportion nonconforming $P = 1/N \sum_{i=1}^N X_i = \bar{X}_{\text{lot}}$. Process quality indicator: process proportion nonconforming $\pi = P(X_i = 1)$. Relation between lot and process quality indicator: $\pi = E[P]$, i.e., the expected lot proportion nonconforming equals the process proportion nonconforming.

Nonconformities (discrete measurement) quality model

Item quality indicators: X_i is the number of nonconformities on item i . Lot quality indicator: lot average number of nonconformities $K = 1/N \sum_{i=1}^N X_i = \bar{X}_{\text{lot}}$. Process quality indicator: process average number of nonconformities $\lambda = E[X_i]$. Relation between lot and process quality indicator: $\lambda = E[K]$, i.e., the expected lot average number of nonconformities equals the process average number of nonconformities.

Continuous measurement quality model

Item quality indicators: X_i is a continuous scale measurement, e.g., weight, length, volume, surface, diameter, pressure, tensile strength, and lifetime. Various types of lot and process quality models according to the specific type of application exist, see [11].

Specification range model

A conforming–nonconforming indicator X_i is built from a discrete or continuous measurement X'_i by prescribing a *specification range* $\mathcal{R}$ for X'_i where $X_i = 0$, if $X'_i \in \mathcal{R}$, $X_i = 1$, if $X'_i \notin \mathcal{R}$. Usual specification ranges are $\mathcal{R} = (-\infty; UL]$ with *upper specification limit* UL , $\mathcal{R} = [LL; +\infty)$ with *lower specification limit* LL , $\mathcal{R} = [LL; UL]$ with *two-sided specification limits* LL , UL .

Sampling procedures are classified according to the underlying quality models. *Sampling by attributes* is based on the conforming–nonconforming model or

on the nonconformities quality model. *Sampling by variables* is based on the specification range model. The continuous measurement model is considered in the framework of reliability sampling by **Reliability Sampling**.

Sampling Plans and Sampling Techniques

SPI is implemented according to a *sampling plan*. A *sampling plan* S is defined by the following *design components*:

- (SP1) Sample-size parameters $n_1, n_2, \dots$
- (SP2) A sampling rule which prescribes how to sample.
- (SP3) Sample statistics $t_1, t_2, \dots$ to evaluate the samples.
- (SP4) Decision parameters.
- (SP5) A decision rule which infers a decision (acceptance or rejection) from the sample statistics and the decision parameters.

The simplest instance is a *single sampling plan* $S = (n, A)$, see **Single Sampling by Attributes and by Variables** a single random sample of size n is taken, the sample quality indicators $Y_1 = X_{i_1}, \dots, Y_n = X_{i_n}$ are evaluated by a statistic $t(Y_1, \dots, Y_n)$, the decision is *acceptance* if t lies in the *acceptance region* A , otherwise the decision is *rejection*. Double, multiple and sequential sampling plans allow for several samples to be taken consecutively until a decision is achieved, see **Multiple Sampling Plans**.

The sample should provide unbiased and representative information on the quality of the inspection target (lot or process). This requirement is met by a *random sample*, as described in the sequel.

In a type A procedure, the samples are drawn without replacement from a specified lot of items $1, \dots, N$. Formally, random sampling without replacement from a lot $1, \dots, N$ means that all $\binom{N}{n}n!$ sequences of pairwise different items $i_1, \dots, i_n$ have the same probability to constitute the sample. In practice, a reliable way to guarantee this property proceeds as follows: assign physically numbers 1 through N to the items in the lot, then extract n pairwise different numbers $1 \leq i_1, \dots, i_n \leq N$ from a random number generator as implemented in statistical packages. If the items cannot be numbered explicitly, a variety of provisions can help to exclude

biases and to come close to an ideally random sample, in particular, not to sample from regional or temporal clusters, e.g., from the top or the bottom of the lot, from the first or last items produced.

The sample for a type B procedure may be from a lot as for a type A procedure, or directly from the process without previous assembling into lots. In final inspection, the items can be sampled directly at the end of the manufacturing line. In receiving inspection, the items may be sampled from a continuous stream of just-in-time delivered material or product. Formally, a process random sample has two properties: the item quality indicators $X_{i_1}, \dots, X_{i_n}$ are independent, and the process quality parameter θ remains invariant over the sample. The practical provisions to achieve these properties are the same as in control charting, *see Control Charts, Overview*. In particular, the possibility of shifts in the process quality parameter within the sample should be excluded, and excessive proximity of items should be avoided to exclude **correlation**.

The Operating Characteristic Function of a Sampling Plan

The *operating characteristic function (OC function)* of a sampling plan S is the probability of achieving the decision *acceptance* as a function of the sampling plan parameters (sample sizes, acceptance region), and the quality indicator of the inspection target (lot or process).

The inspection target of a type A procedure is an individual lot of size N with a given value $Q = q$ of the lot quality indicator, e.g., lot proportion nonconforming, or lot average number of nonconformities. In this case, the OC function is the conditional probability

$$L_S(q) = P(\text{accept the lot under } S | Q = q) \quad (1)$$

of acceptance under the condition that the underlying process has provided a lot of quality $Q = q$. The unconditional probability measure P characterizes the underlying process.

The inspection target of a type B procedure is a process characterized by the process quality indicator θ , e.g., process proportion nonconforming, or process average number of nonconformities. In this case, the OC function is the parametric probability

$$L_S(\theta) = P_\theta(\text{accept the lot/process under } S) \quad (2)$$

As a general rule, type B OC functions can be used as an approximation of type A OC functions for large lot size N . For a detailed analysis of OC functions in acceptance sampling, in particular, the relation between process and lot models, *see* [11]. Specific OC functions are discussed in **Single Sampling by Attributes and by Variables, Multiple Sampling Plans, Rectification Sampling Schemes, Continuous Sampling, Reliability Sampling, Variables Sampling under Measurement Error, and Attributes Sampling under Classification Error**.

Protection is a central issue in product assessment: the consumer seeks protection against accepting unsatisfactory quality, the producer wants good quality to be accepted. The protective potential of sampling plans is characterized by properties and quantities related to the OC function. Important quantities are listed and explained by Table 1.

Definition of Quality Levels

Rational product assessment needs a definition of acceptable (satisfactory) and unacceptable (rejectable, unsatisfactory) product quality. Let Γ be the range of the product quality indicator (lot quality indicator $\gamma = q$ or process quality indicator $\gamma = \theta$), e.g., $\Gamma = [0; 1]$ for the proportion nonconforming, $\Gamma = [0; +\infty)$ for the average number of nonconformities or the average measure value in the continuous measurement model. The parameter range is partitioned by $\Gamma = \Gamma_I \cup \Gamma_{II}$ into the disjoint sets Γ_I (acceptable values of the product quality indicator) and Γ_{II} (unacceptable values of the product quality indicator). The separating boundary of Γ_I and Γ_{II} is the *breakeven quality* γ_0 , e.g., the maximum acceptable proportion nonconforming or the maximum acceptable average number of nonconformities.

The choice of a breakeven quality may be based on technical, security or economic reasons. Economic approaches to lot assessment always imply the specification of a breakeven quality. A widely used economic scheme suggested by Moriguti [12] evaluates the decision acceptance and rejection by linear loss functions $C_A(\gamma)$, $C_R(\gamma)$ of the product quality indicator γ . Then the breakeven quality γ_0 is the intersection point of C_A and C_R , *see Economic Sampling Schemes*. Many authors consider the following particular instance of Moriguti's model, *see* [9] or [8]. Let $\gamma = p$ be the lot proportion nonconforming where rejection means rectification of the lot.

Table 1 Characteristic quantities of sampling plans with OC $L(\gamma)$, (lot quality indicator $\gamma = q$ or process quality indicator $\gamma = \theta$)

Notation	Definition
γ_ρ	ρ 100% point defined by $L(\gamma_\rho) \stackrel{!}{=} \rho$, i.e., a quality level γ_ρ is accepted with probability ρ .
CQ	Consumer's quality. A poor quality level from the consumer's point of view which should be accepted with small probability $L(\text{CQ})$ only.
CR	Consumer's risk: the probability $\text{CR} = L(\text{CQ})$ of accepting the quality level CR.
LTPD	Lot tolerance percent defective. A term for the CQ under inspection for lot proportion nonconforming.
LQL	Limiting quality level. Alternative term for CQ.
RQL	Rejectable quality level. Alternative term for CQ.
PQ	Producer's or supplier's quality. Good quality level from the provider's point of view which should be rejected with small probability $1 - L(\text{PQ})$ only.
PR	Producer's or supplier's risk: the probability $\text{PR} = 1 - L(\text{PQ})$ of rejecting the quality level PR.

Let k_1 be the cost of inspecting an item, k the cost of replacing a nonconforming by a conforming item, k_2 the cost from processing a nonconforming item. Then $C_A(p) = (k_2 + k)Np$, $C_R(p) = (k_1 + kp)N$. Hence the breakeven quality is $p_0 = k_1/k_2$.

It is a basic weakness that, except economic schemes like the one described by **Economic Sampling Schemes**, the majority of the popular SPI schemes do not require the explicit specification of breakeven qualities. Instead, the design of such schemes strongly relies on quantities as listed by Table 1. Some of these quantities have some similarity with a breakeven quality, but they are not properly defined as such. See **Acceptance Sampling in Modern Industrial Environments** for a further analysis of the lack of precise definitions of quality levels in customary SPI.

The Design of Sampling Plans

A *design algorithm* allows determining a sampling plan from some specified input parameters. The design algorithm defines a *sampling scheme*. A *sampling table* is a ready-to-use representation of a sampling scheme in the form of a list indexed by values of the input parameters. The input parameters are of the following types: (a) lot descriptors, e.g., lot size; (b) process quality parameters; (c) lot quality parameters; and (d) economic parameters.

An enormous variety of design rules and **sampling schemes** is discussed in literature. We give a brief survey organized by the three major classification issues. For a more extensive treatment see [13].

A design rule is based on an *evaluation index* $I(S, q)$ which evaluates a sampling plan S under lot quality q . Two types of indices have to be distinguished: (a) Statistical indices based on the OC $L_S(q)$ alone. (b) Economic indices integrating cost and profit parameters, e.g., sampling cost, loss or profit incurred from rejecting/accepting a lot, the latter mostly modeled on the basis of Moriguti's [12] linear scheme, see **Economic Sampling Schemes**.

A second classification relates to the assumptions on prior knowledge on product quality, i.e., the assumptions on the distribution function F of the lot quality indicator Q . Three approaches have to be distinguished: (a) no assumptions (b) partial knowledge represented by parameters of the distribution of Q , e.g., the mean, variance, or quantiles. This amounts to assuming F to be a member of a subset Γ of all distribution functions. (c) Complete knowledge about the distribution function of Q (Bayes approach). Assumptions on process quality are particularly relevant for the way of building economic objective functions from economic indices, subsequently exemplified for a loss index $I(S, q)$. Approach (a) leads to the worst case function $I(S) = \max_q I(S, q)$. Approach (b) leads the restricted worst case function $I(S) = \max_{F \in \Gamma} E_F[I(S, Q)]$. Approach (c) leads to the Bayes objective function $I(S) = E_F[I(S, Q)]$. See **Prior Information in Sampling Schemes** for a more detailed analysis of prior knowledge on product quality in SPI schemes.

A third classification relates to the purposes or optimality principles pursued. Three kinds can be distinguished: (a) *Statistical principles* require certain properties of the OC, e.g., prescribing consumer's

risk, consumer's quality, or producer's risk and producer's quality, see Table 1. (b) *Economic principles* require to maximize (minimize) an economic profit (loss) function $I(S)$. See **Economic Sampling Schemes** for an instance of an economic loss function. (c) *Convenience principles* emphasize pragmatic aspects of usability and simplicity of a sampling scheme.

Special SPI Schemes

A large variety of sampling schemes is discussed in literature, see [14] as an extensive reference source. The following schemes are used, usable or useful.

Dodge–Romig plans

Dating back to Dodge's work at Bell Telephone in the late 1920s and through the 1930s. Published in book form in 1941, with a revised edition in 1959, see [7]. Rectification sampling plans of single and double type for lot proportion nonconforming with a mixed economic-statistical design. Strengths: transparent design, prior knowledge on product quality reflected. Weaknesses: no economic motivation for critical design parameters, inadequate for tight quality requirements. See **Rectification Sampling Schemes** for further analysis.

Prescription of two points of the OC function

A simple and intuitive statistical design suggested by Peach-Littauer [15] in 1946. Consumer's quality level CQ, producer's quality level PQ, and upper bounds β for the consumer's risk (CR), α for the producer's risk (PR) are prescribed. Strength: general, only based on the OC. Weaknesses: prior knowledge on lot quality is not reflected, inadequate for tight quality requirements.

Military standard

Originating in sampling tables developed for the US army during World War II by a group of experts headed by H.F. Dodge. Recent versions: MIL-STD-105E [16], issued in 1989 for attributes sampling for lot proportion nonconforming and lot average number of nonconformities, MIL-STD-414 [17] for sampling by variables for lot proportion nonconforming issued in 1957. In revised form, adopted as national standards in many countries and as international standards ISO 2859 and ISO 3951. Strengths: (a) Simple, widely used and accepted by industry. (b) A proper *sampling system*, including single and

multiple sampling, with three degrees of inspection severity and rules for *switching* among these. Weaknesses: (a) No consistent design principle. (b) Vague definition of the quality target AQL (*acceptable quality level*). (c) Prior knowledge on lot quality not reflected. (d) Inadequate for tight quality requirements. See **Attributes Sampling Schemes in International Standards; Variables Sampling Schemes in International Standards** for further analysis.

α -Optimal Sampling Scheme

A transparent economic design suggested by Collani [18] based on Moriguti's [12] linear loss model. Strengths: Consistent economic design, incomplete prior knowledge on lot quality is considered. Weakness: Hitherto no experience from industrial implementation recorded. See **Economic Sampling Schemes** for further analysis.

Joyce Orsini's rules

An economic convenience approach propagated by Deming [8]. Strengths: simple, admitting for no-sampling alternatives, based on an economic and process model. Weaknesses: no thorough design, no experience from industrial implementation recorded.

Single Sampling by Attributes and by Variables

Introduction

Single sampling plans are the simplest instance of a statistical **product inspection** (SPI) procedure. A single sampling plan is defined by a pair (n, c) consisting of the **sample size** n and the *acceptance number* c , and a *sample statistic* t . The decision rule of a single sampling plan prescribes the following steps: (a) n items are sampled at random; (b) the value of the sample statistic t is calculated from the elements of the sample; and (c) *acceptance* is warranted if $t \leq c$, otherwise the decision is *rejection*.

The study of single sampling plans is illustrative for the understanding of **acceptance sampling**. Single sampling exemplifies all basic features of acceptance sampling in a particularly simple and transparent instance. From theoretical optimality criteria, e.g., expected sampling amount, more refined sampling algorithms with several iterative sample runs like double, multiple, and **sequential sampling** plans (see **Multiple Sampling Plans**) are sometimes superior to single sampling. However, these optimality studies ignore administrative barriers and costs which oppose iterative sampling on shop floor. Simplicity and administrative efficiency have made single sampling plans the most popular acceptance sampling technique by far in industrial practice.

The subsequent explanations consider single sampling plans in general. The special case of single sampling plans under rectifying inspection is considered by **Rectification Sampling Schemes** in detail.

Item Quality, Lot Quality, and Process Quality

Consider discrete items $i = 1, 2, \dots$. The product quality model established by **Sampling Inspection of Products** distinguishes three types of quality indicators: (a) The random *quality indicator* X_i associated with each item i . (b) The *lot quality indicator* which is a function of the quality indicators $X_1, \dots, X_N$ of the items $1, \dots, N$ in the

lot. (c) The quality indicator of the lot generating process. The present article restricts attention to the following instances of this product quality model.

Conforming–nonconforming quality model.

Item quality indicators: binary variables $X_i \in \{0, 1\}$ where $X_i = 0$, if item i is conforming, $X_i = 1$, if item i is nonconforming. Lot quality indicator: lot proportion nonconforming $P = 1/N \sum_{i=1}^N X_i = \bar{X}_{\text{lot}}$. Process quality indicator: process proportion nonconforming $\pi = P(X_i = 1)$.

Nonconformities (discrete measurement) quality model.

Item quality indicators: X_i is the number of nonconformities on item i . Lot quality indicator: lot average number of nonconformities $K = \frac{1}{N} \sum_{i=1}^N X_i = \bar{X}_{\text{lot}}$. Process quality indicator: process average number of nonconformities $\lambda = E[X_i]$.

Specification range model.

A conforming–nonconforming indicator X_i is built from a discrete or continuous measurement X'_i by prescribing a *specification range* $\mathcal{R}$ for X'_i where $X_i = 0$, if $X'_i \in \mathcal{R}$, $X_i = 1$, if $X'_i \notin \mathcal{R}$. Usual specification ranges are $\mathcal{R} = (-\infty; UL]$ with *upper specification limit* UL , $\mathcal{R} = [LL; +\infty)$ with *lower specification limit* LL , $\mathcal{R} = [LL; UL]$ with *two-sided specification limits* LL, UL .

Sampling procedures are classified according to the underlying quality models. *Sampling by attributes* is based on the conforming–nonconforming model or on the nonconformities quality model. *Sampling by variables* is based on the specification range model.

Single Sampling Plans and their Operating Characteristic Function

The data basis for decision by a single sampling plan (n, c) is a single *sample* of n items $\iota_1, \dots, \iota_n$ with a corresponding sequence of item quality indicators $X_{\iota_1}, \dots, X_{\iota_n}$. The sample is evaluated by the sample statistic $t = t(X_{\iota_1}, \dots, X_{\iota_n})$. The sample should provide unbiased and representative information on the quality of the inspection target (lot or process). This requirement is met by a *random sample*. Random sampling from lots and processes is discussed by **Sampling Inspection of Products**.

2 Single Sampling by Attributes and by Variables

Table 1 Sample statistics and OC functions of single sampling plans (n, c) by attributes

Sampling for proportion nonconforming		
Sample statistic	$t = \sum_{j=1}^n X_{t_j}$ number of nonconforming items in the sample $X_{t_1}, \dots, X_{t_n}$	
Type A	Inspection target:	lot proportion nonconforming p
	Hypergeometric OC:	$P(t \leq c) = L_{N,n,c}(p) = \sum_{m=0}^c \frac{\binom{Np}{m} \binom{N(1-p)}{n-m}}{\binom{N}{n}}$
Type B	Inspection target:	process proportion nonconforming π
	Binomial OC:	$P(t \leq c) = L_{n,c}(\pi) = \sum_{m=0}^c \binom{n}{m} \pi^m (1-\pi)^{n-m}$
Poisson approximation	Inspection target:	lot or process proportion nonconforming $q = p$ or $q = \pi$
	Poisson OC:	$P(t \leq c) = L_{n,c}^*(q) = \sum_{m=0}^c \frac{(nq)^m}{m!} \exp(-nq)$
Sampling for average number of nonconformities		
Sample statistic	$t = \sum_{j=1}^n X_{t_j}$ number of nonconformities on items in the sample $X_{t_1}, \dots, X_{t_n}$	
Type A	Inspection target:	lot average number of nonconformities k
	Negative hypergeometric OC:	$P(t \leq c) = \sum_{m=0}^c \frac{\binom{n+m-1}{n-1} \binom{N(1+k)-n-m-1}{N-n-1}}{\binom{N(1+k)-1}{N-1}}$
Type B	Inspection target:	process average number of nonconformities λ
	Poisson OC:	$P(t \leq c) = L_{n,c}^*(\lambda) = \sum_{m=0}^c \frac{(n\lambda)^m}{m!} \exp(-n\lambda)$

The *operating characteristic Function (OC function)* of a sampling plan (n, c) is the probability of achieving the decision *acceptance* as a function of the sampling plan parameters n, c , and the parameters of the inspection target (lot or process).

Type A product inspection is distinguished from type B product inspection, *see Sampling Inspection of Products*. The inspection target of a type A procedure is an individual lot of size N with a given value $Q = q$ of the lot quality indicator, e.g., lot proportion nonconforming, or lot average number of nonconformities. In this case, the OC function is the conditional probability

$$L_{N,n,c}(q) = P(\text{accept} | Q = q) = P(t \leq c | Q = q) \quad (1)$$

where the unconditional probability measure P characterizes the underlying process.

The inspection target of a type B procedure is the product generating process characterized by the process quality indicator θ , e.g., process proportion

nonconforming, or process average number of nonconformities. In this case, the OC function is the parametric probability

$$L_{n,c}(\theta) = P_\theta(\text{accept}) = P_\theta(t \leq c) \quad (2)$$

As a general rule, type B OC functions can be used as an approximation of type A OC functions for large lot size N . For a detailed analysis of OC functions in acceptance sampling, in particular, the relation between process and lot models, see [1].

The sample statistics and OC functions of single sampling plans by attributes are listed in Table 1. Figure 1 displays the OC functions for plans for lot proportion nonconforming and for lot average number of defects. The plans are taken from MIL-STD-105E, normal inspection, inspection level II, AOQ of 1% for proportion nonconforming, 10% for average number of defects. The examples show that even for moderate lot size the difference between the type A and type B OCs is very small. Sampling by variables is discussed in the next section.

Figure 1 OC functions of the single sampling plan $(n, c) = (32, 1)$ for proportion nonconforming p and $(n, c) = (32, 7)$ for average number of defects k . For type A plans the lot size is $N = 160$

Specifications	X' with cdf F	X' with normal distribution $N(\mu, \sigma^2)$
One-sided upper UL	$\pi_U = F(X' > UL)$	$\pi_U = 1 - \Phi\left(\frac{UL - \mu}{\sigma}\right) = \Phi\left(\frac{\mu - UL}{\sigma}\right)$
	$\pi_{L,U} = \pi_L + \pi_U$	$\pi_{L,U} = \Psi_\sigma\left(\mu - \frac{LL + UL}{2}\right)$ where
Two-sided $LL < UL$	$= F(X' < LL)$ $+ F(X' > UL)$	$\Psi_\sigma(x) = \Phi\left(\frac{1}{\sigma}\left(\frac{LL - UL}{2} - x\right)\right)$ $+ \Phi\left(\frac{1}{\sigma}\left(x + \frac{LL - UL}{2}\right)\right)$

Single Sampling by Variables

Sampling by variables is based on the specification range model exposed above. Intrinsically, sampling by variables is a type B procedure where the inspection target is the process proportion nonconforming π . In the specification range model, π can be expressed with the cumulative distribution function (cdf) of the underlying continuous measurement quality indicators X' in the way expressed by Table 2. Accordingly, the implementation of sampling by variables requires that at least the shape of the cdf of the X'_i from the process is stable and known. This requires a good and reliable knowledge about the properties of the process. Without such knowledge, variables plans should not be used, see the remarks on variables sampling by [2].

In a large variety of cases, a **normal distribution** $N(\mu, \sigma^2)$ can serve at least as a good approximation of the distribution of X'_i . Thus the design of sampling plans by variables for this situation is particularly interesting. Table 2 shows the functional relationship between the process proportion nonconforming π , and process mean μ and process variance σ^2 . Hence statistical inference on π is equivalent to statistical inference on μ and σ^2 based on an independent random sample of measurements $X'_{t_1}, \dots, X'_{t_n}$. The inference assumes that μ and σ^2 are constant for the lot or process segment under consideration, and hence in particular for the sample. Unsatisfactory process proportion nonconforming π can result either from an inappropriate value of μ or from an inappropriate value of σ^2 . The sample statistics used for a single sampling plan (n, c) are based on estimating μ by the sample mean $\bar{X}'_{\text{sample}}$ and σ^2 , if it is unknown, by the

Two-sided specification limits $LL < UL$	
Sample statistic	$t = \left \frac{\bar{X}'_{\text{sample}} - \frac{LL+UL}{2}}{S} \sqrt{n} \right $
OC function	$L_{n,c}(\pi_{L,U}) = F_{\delta}(c) - F_{\delta}(-c)$ where $\delta = \frac{\Psi_{\sigma}^{-1}(\pi_{L,U})}{\sigma} \sqrt{n}$, and where $\Psi_{\sigma}^{-1}(\pi_{L,U})$ is the positive inverse of the function Ψ_{σ} defined by Table 2

sample variance S^2 , see Tables 3 and 4. The sample statistics and OC functions for single sampling plans by variables are displayed by Table 3 for the situation of known process variance σ^2 , and by Table 4 for the situation of unknown process variance σ^2 . The tables consider the case of a one-sided upper limit UL and two-sided limits $LL < UL$. The case of a one-sided lower limit LL can be reduced to the case of an upper limit by considering measurements $Y'_i = -X'_i$ and the upper limit $UL = -LL$.

A type A interpretation of variables sampling, to inspect for lot proportion nonconforming, requires a considerable caution. Two aspects are intuitively evident: there is no functional relationship between the process mean μ and lot proportion nonconforming,

and the test statistics suggested by Tables 3 and 4 do not provide suitable information on lot proportion nonconforming. In fact, the following phenomena can occur under a type A use of sampling by variables. (a) Rejection of the lot although the actual sample contains no nonconforming items. (b) Rejection of lots containing 100% conforming items. (c) In case of two-sided specification limits: acceptance of lots containing 100% nonconforming items under 100% inspection. These phenomena have been recorded and analyzed by many authors, e.g. [3–5]. If the focus is on the proportion nonconforming in individual single lots, sampling by attributes should rather be used instead of sampling by variables. To eliminate the specific problems of the two-sided case, various

authors have suggested to use two separate one-sided variables sampling plans instead of a two-sided variables plan, see [3].

Designing a Single Sampling Plan as a Test of Significance

Before implementing **inspection policies**, *acceptable (satisfactory)* and *unacceptable (unsatisfactory)* quality levels should be defined. Consider a lot or process quality indicator of the type *The smaller the better*, e.g., lot or process proportion nonconforming, lot or process average number of defects. In this case, a so-called breakeven quality level q_0 distinguishes acceptable quality with $q < q_0$ from unacceptable quality with $q > q_0$. The motivation of a breakeven quality by an economic model is discussed in **Sampling Inspection of Products and Economic Sampling Schemes**.

With respect to a breakeven quality, decision on acceptance and rejection amounts to a test of the hypothesis $H: q \leq q_0$ against the alternative $K: q > q_0$. The ideal test with $L(q) = 1$ for $q < q_0$ and $L(q) = 0$ for $q > q_0$ can be achieved by 100% inspection only. Sampling inspection involves error, only the probabilities of erroneous decisions can be controlled. In industrial practice, submission of

acceptable quality can be considered as the regular case. Hence, the test of H against K can be considered as a test of significance where only the probability of erroneous rejection of H is controlled by requiring $1 - L(q) \leq \alpha$ for $q \leq q_0$. Although this design approach determines only one of the two sampling plan parameters it can be useful in specific situations.

Modern quality requirements are very strict. **Six Sigma** approaches discuss proportion nonconforming values down to a few parts per million. For such situations, only acceptance number $c = 0$ is tolerable. The sample size of acceptance number zero plans can be calculated from the requirement $1 - L(q) \leq \alpha$ for $q \leq q_0$.

Inspection for lot proportion nonconforming p .

Let p_0 be the breakeven quality. For a large lot, the hypergeometric OC $L_{N,n,c}(p)$ can be approximated by the binomial OC $L_{n,c}(p)$, see Table 1. The requirement $1 - L_{n,0}(p_0) \leq \alpha$ leads to the sample size $n = \ln(1 - \alpha) / \ln(1 - p_0)$.

Inspection for lot average number of defects k .

Let k_0 be the breakeven quality. For a large lot, the negative hypergeometric OC $L_{N,n,c}(k)$ can be approximated by the Poisson OC $L_{n,c}(k)$, see Table 1. The requirement $1 - L_{n,0}(k_0) \leq \alpha$ leads to the sample size $n = -\ln(1 - \alpha) / k_0$.

Table 5 Variables sampling plans (n, c) with prescribed values $L_{n,c}(\pi_1) \geq 1 - \alpha$, $L_{n,c}(\pi_2) \leq \beta$. Φ is the distribution function of the standard normal distribution $N(0, 1)$

One-sided upper specification limit UL , process variance σ^2 known

Acceptance number c	$\frac{\Phi^{-1}(1 - \pi_1)\Phi^{-1}(\beta) - \Phi^{-1}(1 - \pi_2)\Phi^{-1}(1 - \alpha)}{\Phi^{-1}(1 - \pi_1) - \Phi^{-1}(1 - \pi_2)}$
Two-sided specification limits $LL < UL$, process variance σ^2 known (approximate solution)	
Sample size n	Positive integer nearest to $\left(\frac{\Phi^{-1}(1 - \alpha) - \Phi^{-1}(\beta)}{\Phi^{-1}(1 - \pi_1) - \Phi^{-1}(1 - \pi_2)} \right)^2$
Acceptance number c	$\frac{UL - LL}{2\sigma} \sqrt{n} + \frac{\Phi^{-1}(1 - \pi_1)\Phi^{-1}(\beta) - \Phi^{-1}(1 - \pi_2)\Phi^{-1}(1 - \alpha)}{\Phi^{-1}(1 - \pi_1) - \Phi^{-1}(1 - \pi_2)}$
One-sided upper specification limit UL , process variance σ^2 unknown (approximate solution)	
Sample size n	Positive integer nearest to $\frac{4\Phi^{-1}(1 - \alpha)^2 \left(1 + \frac{1}{8}(\Phi^{-1}(1 - \alpha) + \Phi^{-1}(\beta))^2 \right)}{(\Phi^{-1}(1 - \pi_1) - \Phi^{-1}(1 - \pi_2))^2}$
Acceptance number c	$\left(\Phi^{-1}(1 - \alpha) + \Phi^{-1}(\beta) \right) \frac{\sqrt{n}}{2}$

Design by Prescribing Values of the OC Function

Statistical designs of sampling plans consist in prescribing certain properties of the OC function. Important OC-related characteristic quantities of sampling plans like producer's quality (PQ), producer's risk (PR), consumer's quality (CQ), and consumer's risk (CR) are discussed in **Sampling Inspection of Products**. A simple and intuitive statistical design by prescribing two points of the OC function was suggested by Peach and Littauer [6] in 1946. A good quality level q_1 should be accepted with a high-probability $L(q_1) \geq 1 - \alpha$. A poor quality level q_2 should be accepted with a low-probability $L(q_2) \leq \beta$. Often, $q_1 = \text{PQ}$ is identified as the producer's quality, and the requirement $L(q_1) \geq 1 - \alpha$ imposes the upper limit $1 - L(\text{PQ}) \leq \alpha$ on the PR. $q_2 = \text{CQ}$ is identified as the consumer's quality, and the requirement $L(q_2) \leq \beta$ imposes the upper limit $L(\text{CQ}) \leq \beta$ on the CR. The two points design is made unique by requiring to choose the sampling plan (n, c) with the smallest sample size n whose OC satisfies both the constraints.

For single sampling by attributes, the acceptance number c is an integer. The two points design can be determined by a simple iterative search algorithm. An efficient algorithm is suggested by Peach and Littauer [6]. In case of single sampling by variables, the solution can be given explicitly, see Table 5. A derivation is given by Uhlmann [7]. The table considers one-sided and two-sided plans for process variance σ^2 known, and one-sided plans for process variance σ^2 unknown. The situation is considerably

involved for two-sided plans under unknown process variance σ^2 where often the application of two one-sided plans is recommended. For the latter case, [7] derives an approximate solution for the two points design.

Multiple Sampling Plans

Introduction

Under a **single sampling plan** (*see Single Sampling by Attributes and by Variables*), all items for inspection are sampled in one go, and the decision of acceptance or rejection is based on the evidence from this unique sample. From an intuitive point of view, there seems to be an opportunity to reduce the total inspection amount, if lot quality is either very good or very bad: Sample and inspect a few items; if the sample quality is very good accept, if it is very bad, reject; if the sample quality is doubtful, sample a few further items. Continue with this procedure, until the quality of the cumulative sample clearly indicates acceptance or clearly indicates rejection. If lot quality is on one of the extreme sides, the total sampling amount required for a sufficiently reliable decision should be smaller than under a single sampling plan.

The above idea leads to so-called iterative or multistage sampling plans with the following two special cases: (a) A *multiple m -stage sampling plan*, where an upper limit of m successive samples is imposed. The simplest case is a *double sampling plan* (two-stage sampling plan) with a maximum of two sampling steps. (b) A *sequential sampling plan*, where sampling may continue until 100% inspection of the lot.

The idea of iterative sampling is old and had already appeared in Dodge's technical reports at Bell Telephone Laboratories in the 1920s and 1930s, *see* [1]. Double and multiple sampling plans are provided by the traditional industrial standards. MIL-STD-105E provides double and seven-stage sampling plans (*see Attributes Sampling Schemes in International Standards*). ISO 2859-1 contains double and five-stage plans (*see Attributes Sampling Schemes in International Standards*). The Dodge–Romig tables

contain double sampling plans (*see Rectification Sampling Schemes*). Sequential sampling plans are provided by ISO 8422 and ISO 8423 (*see Sampling in Industrial Standards*).

Structure and Operation of Multiple Sampling Plans

In principle, multiple sampling plans can be devised for any of the discrete item quality models of statistical process inspection (SPI) (statistical lot inspection) (*see Sampling Inspection of Products* for a survey). As most established schemes of multiple sampling do, we restrict attention to the customary attributes quality models described by Table 1. For a formal exposition of these models *see Sampling Inspection of Products*. Sequential sampling procedures under the specification range model are provided by the standard ISO 8423 (*see Sampling in Industrial Standards*). We consider multiple sampling plans in a type A framework, where the decision target is a finite lot of items $1, \dots, N$. The methods may also be used for type B purposes where sampling and decision is directed toward the lot generating process. *See Sampling Inspection of Products* for the distinction of type A and type B procedures.

A multiple m -stage sampling plan is defined by a triple $(\mathbf{n}, \mathbf{a}, \mathbf{r})$, where $\mathbf{n} = (n_1, \dots, n_m)$ is a sequence of **sample sizes** $n_1, \dots, n_m \geq 1$, $\mathbf{a} = (a_1, \dots, a_m)$ is a sequence of integer *acceptance numbers* $0 \leq a_1 \leq \dots \leq a_m$, $\mathbf{r} = (r_1, \dots, r_m)$ is a sequence of integer *rejection numbers* $1 \leq r_1 \leq \dots \leq r_m$. The m parameters relate to the m stages of the sampling plan as exposed by Table 2. In most **sampling schemes**, e.g., in MIL-STD-105E and ISO 2859, the differences $r_l - a_l, l = 1, \dots, m - 1$, of the rejection and acceptance number have few variation in l .

The sampling and decision algorithm of a multiple m -stage sampling plan is explained by Table 3

Table 1 Attributes quality models

	Conforming–nonconforming	Nonconformities
Item quality indicator	Item is conforming (nondefective) or nonconforming (defective)	Number of nonconformities (defects) on the item
Lot quality indicator	Lot proportion nonconforming p	Lot average number of nonconformities k
Sample statistic t	Number of nonconforming items in the sample	Number of nonconformities on items in the sample

2 Multiple Sampling Plans

Table 2 The parameters of a multiple m -stage sampling plan for the inspection of a lot of size N

Stage	Sample size	Cumulative sample size	Acceptance number	Rejection number
1	n_1	$n_1^{(c)} = n_1$	a_1	$r_1, r_1 \geq a_1 + 2$
2	n_2	$n_2^{(c)} = n_1 + n_2$	a_2	$r_2, r_2 \geq a_2 + 2$
$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$
m	n_m	$n_m^{(c)} = n_1 + \cdots + n_m$	a_m	$r_m, r_m = a_m + 1$
$0 \leq a_1 \leq a_2 \leq \cdots \leq a_m, \quad 1 \leq r_1 \leq r_2 \leq \cdots \leq r_m, \quad n_1 + \cdots + n_m \leq N$				

Table 3 The sampling and decision algorithm of a multiple m -stage sampling plan with parameters given by Table 2

Stage	Operation	Decision algorithm
1	Sample n_1 items Calculate sample statistic t_1	$t_1 \leq a_1 \implies$ terminate, accept $t_1 \geq r_1 \implies$ terminate, reject $a_1 + 1 \leq t_1 \leq r_1 - 1 \implies$ continue with stage 2
2	Sample n_2 items Calculate sample statistic t_2	$t_1 + t_2 \leq a_2 \implies$ terminate, accept $t_1 + t_2 \geq r_2 \implies$ terminate, reject $a_2 + 1 \leq t_1 + t_2 \leq r_2 - 1 \implies$ continue with stage 3
$\vdots$	$\vdots$	$\vdots$
m	Sample n_m items Calculate sample statistic t_m	$t_1 + \cdots + t_m \leq a_m \implies$ terminate, accept $t_1 + \cdots + t_m \geq r_m \implies$ terminate, reject

where the sample statistics t_l conform to the quality models as explained by Table 1. Because of $a_m = r_m - 1$, the algorithm terminates with certainty at stage m , either with acceptance or with rejection.

In most cases, it is not the proper act of sampling in the sense of selecting items from the lot, which involves costs, but rather the act of inspecting the items to calculate the test statistic (number of nonconforming items or total number of nonconformities in the sample). Inspection costs can be reduced by *curtailed inspection*. Two curtailment techniques exist: (a) Total curtailment: At each stage l , the items in the sample are successively inspected, and as soon as the cumulative number $t_1 + \cdots + t_{l-1} + t_{l,j}$ of nonconforming items or the number of nonconformities found until the j th inspected item equals r_l , inspection is stopped and the lot is rejected. (b) Second-stage curtailment: Starting with curtailment in stage 2 only, so as to obtain an unbiased estimator of the lot quality indicator from the first stage.

Performance Measures of Multiple Sampling Plans

The OC (operating characteristic) function of a type A m -stage sampling plan (n, a, r) is the conditional probability $L_{n,a,r}(q) = P(\text{accept the lot} | \text{lot quality indicator} = q)$ of accepting the lot under the condition that the lot quality indicator (lot proportion nonconforming or lot average number of defects) adopts a value q (see **Sampling Inspection of Products** for a general introduction). Table 4 explains and displays the OC function $L_{n,a,r}(p)$ as a function of the lot proportion nonconforming p under the conforming–nonconforming quality model, and the OC function $L_{n,a,r}(k)$ as a function of the lot average number of nonconformities k under the nonconformities quality model. The OC functions and further performance measures, see below, are expressed by means of stage l probabilities $A_{n,a,r,l}(q)$, $R_{n,a,r,l}(q)$, $T_{n,a,r,l}(q)$ as explained by Table 4. From a type A view, the probabilities

Generic formulas	
$A_{n,a,r,l}(q)$	$A_{n,a,r,l}(q) = P(\text{plan } (n, a, r) \text{ accepts in stage } l \mid \text{lot quality indicator} = q) =$ $\sum_{\substack{0 \leq j_1 \leq n_1, \dots, 0 \leq j_l \leq n_l \\ a_i + 1 \leq j_1 + \dots + j_i \leq r_i - 1, i=1, \dots, l-1 \\ j_1 + \dots + j_l \leq a_l}} \rho_{n,a,r,j_1, \dots, j_l}(q)$
$R_{n,a,r,l}(q)$	$R_{n,a,r,l}(q) = P(\text{plan } (n, a, r) \text{ rejects in stage } l \mid \text{lot quality indicator} = q) =$ $\sum_{\substack{0 \leq j_1 \leq n_1, \dots, 0 \leq j_l \leq n_l \\ a_i + 1 \leq j_1 + \dots + j_i \leq r_i - 1, i=1, \dots, l-1 \\ j_1 + \dots + j_l \geq r_l}} \rho_{n,a,r,j_1, \dots, j_l}(q)$
$T_{n,a,r,l}(q)$	$T_{n,a,r,l}(q) = P(\text{plan } (n, a, r) \text{ terminates in stage } l \mid \text{lot quality indicator} = q) =$ $A_{n,a,r,l}(q) + R_{n,a,r,l}(q)$
OC function	$L_{n,a,r}(q) = P(\text{sampling plan } (n, a, r) \text{ accepts} \mid \text{lot quality indicator} = q) =$ $A_{n,a,r,1}(q) + \dots + A_{n,a,r,m}(q)$
ASN function	$ASN_{n,a,r}(q) = E[\text{random cumulative sample size} \mid \text{lot quality indicator} = q] =$ $\sum_{l=1}^m n_l \sum_{j=l}^m T_{n,a,r,j}(q)$
m -stage sampling plan (n, a, r) for lot proportion nonconforming p	
Hypergeometric	$\rho_{n,a,r,j_1, \dots, j_l}(p) = \prod_{r=1}^l \frac{\binom{Np - (j_1 + \dots + j_{r-1})}{j_r} \binom{N - (n_1 + \dots + n_{r-1}) - (Np - (j_1 + \dots + j_{r-1}))}{n_r - j_r}}{\binom{N - (n_1 + \dots + n_{r-1})}{n_r - j_r}}$
Binomial	$\rho_{n,a,r,j_1, \dots, j_l}(p) = \binom{n_1}{j_1} \dots \binom{n_l}{j_l} p^{j_1 + \dots + j_l} (1-p)^{n_1 + \dots + n_l - j_1 - \dots - j_l}$
Poisson	$\rho_{n,a,r,j_1, \dots, j_l}(p) = \frac{n_1^{j_1}}{j_1!} \dots \frac{n_l^{j_l}}{j_l!} p^{j_1 + \dots + j_l} \exp(-(n_1 + \dots + n_l)p)$
m -stage sampling plan (n, a, r) for lot average number of nonconformities k	
Poisson	$\rho_{n,a,r,j_1, \dots, j_l}(k) = \frac{n_1^{j_1}}{j_1!} \dots \frac{n_l^{j_l}}{j_l!} k^{j_1 + \dots + j_l} \exp(-(n_1 + \dots + n_l)k)$

given by Table 4 for the two attributes quality models are approximations: the hypergeometric distribution is approximated by the binomial distribution, and the negative hypergeometric distribution is approximated by the Poisson distribution, compare the approximations discussed by **Single Sampling by Attributes and by Variables**. The approximations are tolerable for large lot size N . From a type B view, where the lot generating process is the inspection target, the values given by Table 4 are exact. For a detailed analysis, see [2] or [3].

Under multiple sampling, the actually reached cumulative sample size SN is a random variable in which $SN = n_l^{(c)} = n_1 + \dots + n_l$ iff the procedure terminates at stage l , $1 \leq l \leq m$. A suitable performance measure is the expectation $E[SN]$, the so-called average sample number (ASN), which as a function of the sampling plan parameters and the lot quality indicator is denoted as $ASN_{n,a,r}(q)$.

$ASN_{n,a,r}(q)$ can be calculated by the termination probabilities $T_{n,a,r,1}(q), \dots, T_{n,a,r,m}(q)$ in the manner described by Table 4.

Under curtailed inspection, the random cumulative sample size is $SN = n_l^{(c)} = n_1 + \dots + n_l$, if the procedure terminates at stage l with acceptance, and $SN = n_1 + \dots + n_{l-1} + j$, if the procedure terminates at stage l with rejection, where j is the smallest number such that $t_1 + \dots + t_{l-1} + j = r_l$. Formulas for the $ASN = E[SN]$ under curtailment are provided by Montgomery [4] and in more technical detail by Uhlmann [2] and Hald [5].

Sequential Sampling

Sequential sampling plans and the corresponding decision algorithm are defined in a way analogous to the definition of multiple sampling plans, except

4 Multiple Sampling Plans

that there is no upper limit m imposed on the number of sampling stages, i.e. the triple (n, a, r) consists of infinite sequences. Tables 2 and 3 remain valid for explaining the parameters and the decision algorithm, except that there is no terminating restriction.

Usually, sequential sampling plans are simplified by the following two assumptions: (a) The stage sample sizes are identical, i.e. $n = n_1 = n_2 = \dots$ (b) The differences of rejection and acceptance numbers remain invariant, i.e., $d = r_l - a_l$ for $l = 1, 2, \dots$. Under the simplifications (a) and (b), a sequential sampling plan can be defined by a tuple (n, s, h_1, h_2) where n is the invariant sample size, s is a *slope*, h_1, h_2 are *increments*, and where $a_l = sln - h_1$ are the acceptance numbers, $r_l = sln + h_2$ the rejection numbers. The operation of a sequential sampling plan (n, s, h_1, h_2) is illustrated by Table 5. Plans with sample size $n \geq 2$ are called *group sequential plans*. *Item-by-item sequential plans* (*unit sequential plans*) with $n = 1$, i.e. only one item is drawn at each stage, are very common. If there are no economic or administrative restrictions for the sample (group) size n in a group sequential plan, Cowden [6] suggests the use of the smallest group size under which acceptance is possible in the first stage (first sample), i.e. n is the smallest integer exceeding h_1/s .

As for multiple sampling, the essential performance measures are the OC and the ASN function. The OC function of a type A sequential sampling plan (n, s, h_1, h_2) is the conditional probability $L_{n,s,h_1,h_2}(q) = P(\text{accept the lot} \mid \text{lot quality indicator} = q)$ of accepting the lot under the condition that the lot quality indicator (lot proportion nonconforming or lot average number of defects) adopts a value q .

The ASN function is $ASN_{n,s,h_1,h_2}(q) = E[\text{cumulative sample size} \mid \text{lot quality indicator} = q]$. In principle, the formulas given in Table 4 can be adapted to the sequential case by substituting finite by infinite sums. However, the resulting expressions are difficult both for theoretical and for numerical analysis. Better closed expressions and approximations are provided by [5].

Design by Prescribing Two Points of the OC Function

The design of sampling plans based on prescribing two points of the OC function is described for simple sampling plans by **Single Sampling by Attributes and by Variables**. The same approach can be used for designing iterative sampling plans: a good quality level q_1 should be accepted with a high probability $L(q_1) \geq 1 - \alpha$, and a poor quality level q_2 should be accepted with a small probability $L(q_2) \leq \beta$, where $0 < \beta < 1 - \alpha$.

For multiple sampling plans, the two-points design does not determine a unique plan among all plans (n, a, r) . Additional constraints are necessary to assure uniqueness, e.g. requiring that the sample sizes satisfy a geometric progression $n_{i+1} = cn_i$. See [7] for a survey.

For sequential item-by-item sampling plans $(1, s, h_1, h_2)$, the simple approximate solution developed by [8] is displayed by Table 6. The results obtained by Wald [8] include approximations to the OC and ASN functions of the two-points design plan $(1, s, h_1, h_2)$.

Iterative Sampling with Rectification

Under rectifying sampling for lot proportion nonconforming, a rejected lot is subject to 100% inspection.

Table 5 The sampling and decision algorithm of a sequential sampling plan (n, s, h_1, h_2)

Stage	Operation	Decision algorithm	
1	Sample n items Calculate sample statistic t_1	$t_1 \leq s \cdot n - h_1$	$\implies$ terminate, accept
		$t_1 \geq s \cdot n + h_2$	$\implies$ terminate, reject
		$s \cdot n - h_1 < t_1 < s \cdot n + h_2$	$\implies$ continue with stage 2
$\vdots$	$\vdots$	$\vdots$	
l	Sample n items Calculate sample statistic t_l	$t_1 + \dots + t_l \leq sln - h_1$	$\implies$ terminate, accept
		$t_1 + \dots + t_l \geq sln + h_2$	$\implies$ terminate, reject
		$-h_1 < t_1 + \dots + t_l - sln < h_2$	$\implies$ continue with stage $l + 1$
$\vdots$	$\vdots$	$\vdots$	

Table 6 Design of an item-by-item sequential sampling $(1, s, h_1, h_2)$ plan by prescribing two points of the OC function

Design rule	$0 < q_1 < q_2 < 1, \quad 0 < \beta < 1 - \alpha, \quad L_{1,s,h_1,h_2}(q_1) \geq 1 - \alpha \geq \beta \geq L_{1,s,h_1,h_2}(q_2)$	
Item-by-item plan $(1, s, h_1, h_2)$ for lot proportion nonconforming p		
Increments	$h_1 = \frac{\log(1-\alpha)-\log(\beta)}{\log\left(\frac{p_2}{p_1}\right)+\log\left(\frac{1-p_1}{1-p_2}\right)}, \quad h_2 = \frac{\log(1-\beta)-\log(\alpha)}{\log\left(\frac{p_2}{p_1}\right)+\log\left(\frac{1-p_1}{1-p_2}\right)}$	
Slope	$s = \frac{\log(1-p_1)-\log(1-p_2)}{\log\left(\frac{p_2}{p_1}\right)+\log\left(\frac{1-p_1}{1-p_2}\right)}$	
Item-by-item plan $(1, s, h_1, h_2)$ for lot average number of nonconformities k		
Increments	$h_1 = \frac{\log(1-\alpha)-\log(\beta)}{\log(k_2)-\log(k_1)}, \quad h_2 = \frac{\log(1-\beta)-\log(\alpha)}{\log(k_2)-\log(k_1)}$	
Slope	$s = \frac{k_2-k_1}{\log(k_2)-\log(k_1)}$	
Approximate OC and ASN functions		
Generic OC	$L_{1,s,h_1,h_2}(q) = \frac{\exp(h_2t)-1}{\exp(h_2t)-\exp(-h_1t)}, \quad t = t(q)$	
$q = p$	$t(p)$ defined as the inverse $p(t) = \frac{\exp(st)-1}{\exp(t)-1}$	
$q = k$	$t(k)$ defined as the inverse $k(t) = \frac{st}{\exp(t)-1}$	
Generic ASN	$\frac{h_2-(h_1+h_2)L_{1,s,h_1,h_2}(q)}{q-s},$ to be used with $q = p$ or $q = k$	

All nonconforming items discovered in the sample and, in case of rejection, in the lot are replaced by conforming ones. The performance measures of iterative rectification plans are defined analogously to the performance measures of single rectification plans (*see Single Sampling by Attributes and by Variables*): as a function of the proportion nonconforming p in the submitted lot, the *average outgoing quality* $AOQ(p)$ is the expected value of the lot proportion nonconforming after application of a rectification plan, and the *average total inspection* $ATI(p)$ is the expected value of inspected items. The *average outgoing quality limit* is the maximum $AOQL = \max_{0 \leq p \leq 1} AOQ(p)$. Table 7 displays exact formulas

for multiple sampling plans, and approximate formulas for sequential item-by-item plans designed by prescribing two points of the OC function as shown in Table 6, see [7] for a derivation of the approximations.

Comparison of Single and Iterative Sampling

The intuitive motivation of iterative sampling is a reduction of expected sample size under extreme (very good or very bad) lot quality. For a simple quantitative comparison, one can compare the ASN functions of single and iterative plans which are

Table 7 Performance measures of iterative rectification plans for lot proportion nonconforming p

Multiple m -stage plan $(n, a, r)^{(a)}$	
$AOQ(p)$	$AOQ(p) = \sum_{l=1}^m p \left(1 - \frac{n_1 + \dots + n_l}{N}\right) A_{n,a,r,l}(p)$
$ATI(p)$	$ATI(p) = \sum_{l=1}^m (n_1 + \dots + n_l) A_{n,a,r,l}(p) + N (1 - L_{n,a,r,l}(p))$
Item-by-item sequential plan $(1, s, h_1, h_2)^{(b)}$	
$AOQ(p)$	$AOQ(p) \approx p L_{1,s,h_1,h_2}(p)$
$ATI(p)$	$ATI(p) \approx \frac{L_{1,s,h_1,h_2}(p)(\log(\beta)-\log(1-\alpha))}{p \log\left(\frac{p_2}{p_1}\right) + (1-p) \log\left(\frac{1-p_2}{1-p_1}\right)} + N (1 - L_{1,s,h_1,h_2}(p))$

^(a) See Table 4 for the probabilities $A_{n,a,r,l}(p)$ and the OC $L_{n,a,r,l}(p)$

^(b) Notation and quantities from Table 6

Figure 1 Average sample number $ASN(p)$ for single sampling plan $(69, 1)$ and double sampling plan with $n = (50, 100)$, $a = (0, 3)$, $r = (2, 4)$

matched to have approximately the same OC function. An instance of this comparison under inspection for lot proportion nonconforming p is displayed by Figure 1. For the single sampling plan $(69, 1)$ and the double sampling plan with $n = (50, 100)$, $a = (0, 3)$, $r = (2, 4)$, the OC functions are very close. With respect to the ASN, the double plan is superior to the single plan for p smaller than 0.005 and p larger than 0.06. For the large intermediate range from 0.5 to 6% single sampling is better.

Opposed to the advantage of iterative sampling for extreme lot quality are several disadvantages of iterative sampling: administrative difficulties;

incompetence of inspectors to execute the algorithm correctly; hidden setup sampling costs from repeated sampling, in particular under sequential plans. Iterative methods should be preferred over single sampling only if the product quality history inspires data-based confidence that lot quality is really on one of the extreme sides.

Sampling in Industrial Standards

Evolution of Sampling Standards

During the first few decades of the twentieth century, many industrialized countries including the United States, United Kingdom, Germany, and France had established national standardization bodies that were the forerunners of those that exist today. Early developmental focus was primarily on product standards, especially driven by the demand for goods created during and between the two world wars. With the development of new, generically applicable **quality control** methods such as **control charts** and sampling inspection by the engineers and mathematicians of the Western Electric Company and Bell Telephone Laboratories in the 1920 and 1930s, it would only be a matter of time until the need for standardization of such statistical methods would be necessary in industrial production.

The basis of the earliest standards was a direct result of the expansion of the telephone industry in the United States and the associated demand for high-quality products that made up the complex telephone systems. Through the efforts of Shewhart, Dodge, Romig, and others, sampling methodologies were developed as alternatives to 100% inspection. These efforts resulted in published rules for the use of control charts and tables for sampling inspection in technical journals and books. By the early 1930s, these new methodologies were becoming better known both within the United States and across the ocean, leading to the creation of one of the first official national standards on the subject with Pearson's development of British Standard (BS) BS-600 (see [1], Part I).

With the outbreak of World War II in 1939, the demand for quality products to support the war effort greatly increased. Foreseeing that the United States would likely be drawn into the conflict, the American Standards Association took the initiative to create two standards in May 1941 with respect to quality control and the use of control charts (see [1], Part II). With the United States' formal entry into the war in December 1941, an unprecedented demand for quality goods and products by the military forces became reality. Two options were considered to address this

problem: (a) emphasize training of contractors and require their use of process quality controls, or (b) develop and apply a system of **acceptance sampling** inspection procedures for use by government inspectors. Owing to the urgent need for a practical solution, the primary focus shifted to the development of sampling inspection procedures, although work on process quality control was continued and resulted in a third standard on the subject in April 1942.

By July 1942, the US Army Service Forces had produced the first forerunner to a sampling inspection standard *via* its document "Standard Inspection Procedures – Quality Control". The goals of these attribute-based sampling plans were to enable the military to quickly obtain enormous quantities of necessary materials that were both reliable and safe, while attempting to treat all vendors fairly and alike. To facilitate implementation, a relatively simple approach was devised that was based on acceptable quality levels and a method of switching between normal and tightened inspection in response to submitted product quality levels. Research on sampling inspection remained a priority during the war years, leading to the development of sampling plans based on producer's risk quality and consumer's risk quality for both sampling by attributes and sampling by variables, and the creation of the theory for **sequential sampling**. Sampling plans based on this research were adopted into a US Navy standard issued in 1945.

Following the war, the focus shifted to adopting a more unified approach to **attribute sampling** inspection within the military branches (see [1], Part III). This led to the creation of the Joint Army–Navy standard JAN-STD-105 in 1949. In 1950, this standard was revised and replaced by the now familiar military standard MIL-STD-105A. This standard experienced technical amendments over the years (version B in 1958, C in 1961, D in 1963, and finally E in 1989) but maintained the same basic features. *See Attributes Sampling Schemes in International Standards* for further details.

In parallel to the evolution of the military standard attribute sampling plans, work also commenced on the development of compatible inspection by variables sampling plans. Different branches of the US military had created variables sampling plans as early as 1952 (Navy Ordnance Standard NAVORD OSTD 80) and 1954 (Ordnance Standard (ORD-M603-10)). These standards were replaced by the now well-known MIL-STD-414 in 1957

(see [2] and [3]), based largely on the research in [4]. MIL-STD-414 was designed to complement MIL-STD-105 for product characteristic measurements that could be assumed to follow a **normal distribution**. See **Variables Sampling Schemes in International Standards** for further details.

To address another common quality control situation, the US military also created standards for **continuous sampling** procedures for inspection by attributes, designed for processes producing a continuous stream of products rather than a series of lots. The first standardized procedures were produced by different military branches in the early 1950s, culminating in the issuance of handbooks H-106 and H-107 in the late 1950s, covering multilevel and single-level continuous sampling procedures respectively (see [1], Part IV, and [5]). The procedures from the two handbooks were amalgamated in 1962 to form MIL-STD-1235. Like its counterpart MIL-STD-105, the standard underwent technical amendments over the years (version A in 1974, B in 1981, and finally C in 1988) but maintained the same basic features. See **Continuous Sampling** for further details.

Movement from Military to National to International Standards

With the growth of international commerce in the years following World War II, the sampling standards that were originally focused on military procurement of goods found themselves being increasingly used by industry in general for all sorts of products. With the broadened application of the standards, it was evident that a transition from the traditional military custodianship of the sampling standards to civilian bodies formed specifically for the purpose of developing and maintaining standards in general would eventually take place. Although in some countries sampling standards had been sponsored by national standards bodies as early as the 1930s and 1950s (notably the United Kingdom and Japan respectively), the transition began to pick up pace throughout the 1970s and 1980s. For example, in 1971 the American National Standards Institute (ANSI) introduced its version of MIL-STD-105D designated as ANSI Z1.4. The following year, ANSI had incorporated MIL-STD-414 under the new designation of ANSI Z1.9. Another important milestone occurred in 1974 with the International Organization for Standardization (ISO) issuing ISO 2859

as an international replacement for MIL-STD-105D. In the years following these initial developments, military organizations such as the US Department of Defense and the UK Ministry of Defence have adopted policies of discontinuing development and maintenance of standards where appropriate civilian standards are available. Most of the well-known military standards have been formally canceled as a result with notices to use the replacement national standards.

Over the past few decades, the development and maintenance of sampling standards has increasingly shifted away from national bodies toward international sponsorship. As most national standards bodies are members of ISO and generic sampling standards are of interest to many countries, it has become more economical for interested parties to collaborate in the development of these standards as delegates of their national standards bodies on international technical committees. Member countries then often adopt the resulting ISO standard as their national standard.

For the development of general statistical standards, ISO has created Technical Committee TC69, with Subcommittee SC5 specifically responsible in the area of acceptance sampling. ISO TC69/SC5 is the custodian of more than a dozen generic standards related to sampling inspection; these are briefly described in the following section. Refer to [6] for full titles and additional information.

International Sampling Standards (ISO)

ISO 2859 Sampling Procedures for Inspection by Attributes

ISO 2859 was the first generic sampling standard created by ISO and was developed to serve as the international replacement for MIL-STD-105D. Since its introduction in 1974 as a single document, the standard has now evolved into a multipart series. The primary application of the series is in the production of a continuing series of lots, providing single, double, multiple, and sequential **sampling schemes** for this purpose. However, Part 2 of the series provides sampling plans for isolated lots that were designed to intertwine with the design of the continuing series philosophy of Parts 1, 3, and 5. Part 4 of this series was designed to introduce an auditing component to the system to support the movement to formal **quality management** systems employing the sampling

schemes of this series. Part 10 of this series was created to provide a general introduction to acceptance sampling by attributes and provides a brief summary of the attribute sampling schemes and plans used in Parts 1 through 5. It also provides guidance on the selection of the appropriate inspection system for use in a particular situation. Refer to **Attributes Sampling Schemes in International Standards** for technical details.

ISO 3951 Sampling Procedures for Inspection by Variables

ISO 3951 was developed to serve as the international replacement for MIL-STD-414. Since its introduction in 1981 as a single document, the standard has now evolved into a multipart series. To the extent that is technically possible, the ISO 3951 series is consistent with the goals and philosophies of its counterparts in the ISO 2859 series. See **Variables Sampling Schemes in International Standards** for further details.

ISO 8422 and 8423 Sequential sampling plans (attributes and variables)

These two standards contain sequential sampling plans and procedures for inspection of discrete items by attributes and by variables for percent nonconforming for known standard deviation, respectively. These sampling standards are similar to the ISO 2859-5 and ISO 3951-5 sampling schemes but the plans are indexed in terms of the producer's risk point and the consumer's risk point rather than by acceptance quality limit (AQL), and therefore provide specific control of these risks whereas the AQL plans rely on switching rules to alter the risks in response to changing process quality. The standards are designed primarily for the analysis of samples taken from stable processes but the attributes standard may also be used for acceptance sampling of an isolated lot when its size is large, and the expected fraction nonconforming is small (significantly smaller than 10%). The sampling plans are applicable where the extent of nonconformity is expressed in terms of proportion nonconforming. The attributes plans may

also be used where nonconformity is expressed on a per item basis (per 100 items).

ISO 13448 Acceptance Sampling Procedures Based on the Allocation of Priorities Principle (APP)

Part 1 of this series gives guidance and explains the methodology of the allocation of priorities principle (APP). Its principal premise is to permit the use of any type of prior objective and subjective information when determining the appropriate sampling plan to be used in a given situation. As a result, when the information suggests that the production quality is very high and the supplier is trustworthy, no sampling inspection may be required. Conversely, when the opposite situation is suggested, 100% inspection may be warranted. Examples of such information are inspection results for previous lots, certification of the supplier's quality management system as being in conformity with ISO 9001, quality control data, and customers' subjective estimates of the supplier's capability to provide the desired quality, all of which may be summarized in a trust level. This allows a reduction or increase in the required **sample size** as the customer's trust in the producer increases or decreases, as the case may be. In addition, when successive inspections of the same lot are carried out by different parties (i.e., customer, supplier, and/or a third party), the APP procedures allow parties to choose sampling plans commensurate with their differing resources and inspection capabilities. The choice of sampling plans needs only to be coordinated among the involved parties with respect to the customer's or supplier's risks in order to reduce the possibilities of contradictory results and wasted resources when quality is acceptable.

Part 2 provides **single sampling** by attributes plans for inspection of lots in accordance with the guidelines of Part 1. All subjective and objective information pertaining to the supplier's capability to provide the desired quality may be taken into account by the customer or a third party when deciding on his sampling plan, thus allowing smaller sample sizes when the information is favorable. This information is categorized in six trust levels ranging from full trust to a lack of any reliable information with respect to the supplier's quality capability with a seventh special trust level for important characteristics requiring 100% inspection. Guided by the trust information and

4 Sampling in Industrial Standards

associated consumer risks, permissible plans may be selected from the standard according to an index of 14 NQL (normative [or guaranteed] quality limits) values ranging geometrically from 0.15 to 65 and over. Rules for successive sample inspections on the same lot by different parties (i.e., supplier, customer, and/or a third party) are also provided.

ISO 14560 Acceptance Sampling Procedures by Attributes – Specified Quality Levels in Nonconforming Items Per Million

This standard specifies, for quality levels expressed as nonconforming items per million items, procedures for estimating the quality level of a single entity (e.g., a lot) and, when the production process is in statistical control, for estimating the process quality level based on evidence from several samples. Procedures are also specified for using this information when selecting a suitable sampling plan so as to verify that the quality level of a given lot does not exceed a stated limiting quality level (LQL). For the case where no prior sample data is available, guidance is given for presuming a process quality level in selecting a plan. The standard also provides incentives for suppliers to improve their quality. The lot acceptance portion of this specification requires larger sample sizes when quality declines and smaller sample sizes when quality improves. The sampling plans are indexed by 24 LQL values ranging from 500 to 100 000 nonconforming items per million items. In the case of a continuing series of lots, sample size is related to a prior estimate of the process quality level and in the case of an isolated lot, sample size is related to a presumed process quality level or that of the first few lots in a series.

ISO 18414 Acceptance Sampling Procedures by Attributes – Accept-Zero Sampling System Based on Credit Principle for Controlling Outgoing Quality

This standard specifies a system of single sampling schemes for lot-by-lot inspection by attributes. All the sampling plans of the system are of accept-zero form, i.e., no lot is accepted if the sample from it contains one or more nonconforming items. The schemes depend on a suitably defined average outgoing quality limit (AOQL) chosen by the user. No restrictions are placed on the choice of the value of the AOQL

or on the sizes of successive lots in the series. This standard's approach intends to induce a supplier, through the economic and psychological pressure of lot nonacceptance and consequent loss of accumulated credit, to attempt to maintain a nonconformity-free process, while assuring, by means of the lowest practicable sample sizes, that the long-term percentage of nonconforming items delivered to the customer or marketplace does not exceed the AOQL. This objective is achieved by a progressive reduction in the sample size in response to good quality history (i.e., increasing credit). The schemes enable the required sample size to be determined on the basis of a simple calculation involving the lot size, the AOQL value, and the accumulated credit, so no tables are required. Owing to the nature of the schemes, this standard is not applicable where inspection is destructive.

ISO 21247 Combined Accept-Zero Sampling Systems and Process Control Procedures for Product Acceptance

This standard provides a set of accept-zero sampling systems and procedures for planning and conducting inspections to assess quality and conformance to specified requirements. It also provides requirements for alternative acceptance methods proposed by the supplier. Such alternative methods would be based upon establishing and implementing an internal prevention-based quality management system as a means of ensuring that all products conform to requirements specified by the contract and associated specifications and standards. In the absence of acceptable alternative methods, the standard presents three types of matched sampling systems for the sampling inspection of product submitted to the customer for acceptance. These systems provide for sampling inspection by attributes, sampling inspection by variables, and for continuous sampling by attributes. The three types of matched sampling systems are indexed by seven specified verification levels and five sample size code letters. Approximately the same level of protection is provided by each of the three types of systems, when using the same code letter and verification level. The supplier has the option to utilize the type of sampling system, at the same verification level, that best suits the production process. The sampling systems and procedures of the standard are not intended for use with destructive tests or where product screening is not feasible or desirable. In such

cases, it permits the sampling strategy to be specified in the contract or product specifications.

It is noteworthy that this standard was developed as a civilian replacement for US Department of Defense (DoD) Test Method Standard MIL-STD-1916 "DoD Preferred Methods for Product Acceptance" and was directly sponsored by DoD resources. The issuance of MIL-STD-1916 in 1996 marked a dramatic change in the US military's general philosophy regarding the role of sampling inspection in quality control, especially with respect to the AQL concept and its implied acceptable levels of non-conforming product. The standard's stated purpose was to encourage product suppliers to submit efficient and effective **process control** (prevention) procedures in place of prescribed sampling (detection) requirements, with emphasis on continuous improvement. MIL-STD-1916 is expected to be canceled as a result of the issuance of ISO 21247.

*Draft International Standard ISO/DIS 24153
Random Sampling and Randomization Procedures*

To ensure the integrity of the results obtained through the application of the various sampling standards, the validity of the random sampling procedures used is critical. Previously, sampling standards had simply specified the need for a sample to be drawn at random, very frequently without identifying how this should be done. Experience of many experts and practitioners has indicated that samples were often drawn in accordance with methods that were inherently biased. This standard was created to fill

the void and provide an authoritative reference for not only sampling inspection situations but various other experimental situations as well. It defines procedures for random sampling and **randomization**, including approaches based on mechanical devices, tables of random numbers, and portable computer algorithms. It also provides information needed to audit the results of a random sampling exercise when required by quality management personnel or regulatory bodies. It is expected that this document will become a full international standard in late 2007.

Attributes Sampling Schemes in International Standards

Introduction

Standardized sampling procedures for the inspection of attribute quality characteristics were developed during World War II by the United States Department of Defense. The first military standard MIL-STD-105A was published in 1950. Updated versions were issued as MIL-STD-105B, MIL-STD-105C and MIL-STD-105D. MIL-STD-105E [1] is the latest version issued in 1989.

Further national and international standards emerged as derivatives of MIL-STD. In 1971, the American Society for Quality (ASQ) introduced the American National Standards Institute ANSI/ASQ Z1.4 as a derivative of MIL-STD105D, the most recent version of ANSI/ASQ Z1.4 [2] issued in 2003 is a modified counterpart of MIL-STD-105E. The US military cancelled MIL-STD-105E by a note in February 1995 and recommended the use of ANSI/ASQ Z1.4. ISO 2859 was the first sampling standard created by the ISO (International Standards Organization) as a derivative of and international alternative to MIL-STD-105. Issued as a single document in 1974, the standard evolved into a series of presently six parts, labeled 1 through 5, and 10, see [3–8]. The present version of ISO 2859 has been adopted as a national standard in many countries, e.g., as BS 6001 in the United Kingdom or as DIN ISO 2859 in Germany.

MIL-STD-105E provided the pattern for all further developments in standardized attributes sampling. The article describes the purpose, design and operation of MIL-STD-105E in detail, and analyzes the relation among MIL-STD-105E and the very similar ISO 2859-1. The further parts of ISO 2859 are briefly reviewed. Further attributes sampling standards are discussed by **Sampling in Industrial Standards**.

Basics of MIL-STD-105 and Derivatives

Three issues are essential for statistical **product inspection** (SPI): the quality model, the control objective, and the quality indices used.

Quality Models

The national and international standards considered below are based on the two attributes quality models of SPI. (a) *Conforming–nonconforming*: items are classified as conforming (nondefective) or nonconforming (defective), the lot quality indicator is the lot proportion nonconforming p , the process quality indicator is the process proportion nonconforming π , and the sample statistic t is the number of nonconforming items in the sample. (b) *Nonconformities*: item quality is determined by the number of nonconformities (defects) of the item, the lot quality indicator is the lot average number of nonconformities k , the process quality indicator is the process average number of nonconformities λ , and the sample statistic t is the number of nonconformities on items in the sample. See **Sampling Inspection of Products** for more information on quality models of SPI.

The Control Objective

Type A product inspection is distinguished from type B product inspection (see **Sampling Inspection of Products**). Type A inspection is designed to control the quality of individual lots: the quality target is the lot quality indicator, and the decision on acceptance or rejection bears on the individual lot. Type B procedures are designed to control the quality of the lot generating process of manufacture, transport and so on. The quality target is the process quality indicator, and the decision on acceptance or rejection refers both to the individual lot and to the lot generating process.

Decidedly, MIL-STD-105 and its derivatives are intended for type B inspection. MIL-STD-105E [1, p. 1] states “These plans are intended primarily to be used for a continuing series of lots or batches.” The control tool directed toward the process of lots are the *switching rules*, as pointed out by ISO 2859-1 [3, p. 13]: “These schemes are intended primarily to be used for a continuing series of lots, that is, a series of lots to allow the switching rules to be applied.” The switching rules are a regime to change between different levels of inspection severity (normal, tightened, reduced) according to *past decisions* on lots, see the more detailed exposition below. However, the switching regime is not designed as a mechanism to convey *previous information* on process quality. The switching regime has two purposes: (a) penalizing poor process quality by high rejection rates,

eventually leading to discontinuation of inspection (rejection without inspection); thus, the consumer is protected against poor quality, and pressure is exerted on the provider to submit satisfactory quality; (b) reducing the inspection cost in cases of proven good process quality.

Using MIL-STD-105E or ISO 2859-1 for the inspection of isolated lots without applying the switching rules contradicts the intrinsic intention of the schemes. There are two options for the inspection of isolated lots under a type A perspective: use the LQ (limiting quality) tables in MIL-STD-105 or ISO 2859-1, or use the specific LQ scheme provided by ISO 2859-2 [4].

Quality Indices: AQL and LQ

The design of sampling plans or **sampling schemes** involves *quality indices*. Commonly, the quality indices are critical levels of the quality target, i.e., the lot or the process quality indicator. MIL-STD-105 and its derivatives use two quality indices: the first index is termed as the acceptance quality level (AQL), in MIL-STD and as *acceptance quality limit* in ISO, and the LQ.

MIL-STD-105E [1, p. 2] defines “When a continuous series of lots is considered, the AQL is the quality level which, for the purposes of sampling inspection, is the limit of a satisfactory process average.” ISO 2859-1 [3, p. 25] defines the AQL as the “quality level that is the worst tolerable process average when a continuing series of lots is submitted for **acceptance sampling**”. The AQL clearly refers to the process quality indicator. However, the definitions are not precise. The operational clauses “for the purposes of sampling inspection” and “submitted for acceptance sampling” are rather confusing. From a business management point of view, the “satisfactory” or “tolerable” process quality level should be defined independently of the inspection aspect as a *breakeven quality*, i.e., a threshold value which separates satisfactory from unsatisfactory process quality levels. In final analysis, the definition of the breakeven quality has to be based on economic criteria. The standards neither mention the concept of a breakeven quality nor give any guidelines to a rational selection thereof. As a consequence, the AQL is mostly not specified on grounds of economic expertise, but stipulated by contracts, or prescribed by convenience of industrial segments, or dictated by authorities, or chosen

arbitrarily. The situation is even more complicated by ISO 2859-1 where the AQL is implicitly identified with the producer’s quality (*see Sampling Inspection of Products*), and high probabilities of acceptance for lots of AQL quality are tabulated. Why should the worst tolerable quality level be accepted with high probability? *See Sampling Inspection of Products and Acceptance Sampling in Modern Industrial Environments* for a further discussion of quality levels.

In MIL-STD-105, the LQ is a secondary index to be used for determining sampling plans with a type A focus [1, p. 9]. The LQ is the primary quality index of ISO 2859-2 [4]. The LQ, also denoted as the consumer’s quality level (CQL) by ISO 2859-1 or as the LTPD (lot tolerance percent defective) by the Dodge–Romig scheme, expresses a limit for tolerable values of the lot quality indicator (lot proportion nonconforming or lot average number of nonconformities) from the consumer’s view. The probability $L_S(LQ)$ of accepting a lot with proportion nonconforming LQ under a sampling plan S is the *consumer’s risk* (CR) (*see Sampling Inspection of Products*), where L_S is the operating characteristic (OC) function of the sampling plan S . The CR should be small. ISO 2859-2 approximately uses the customary value 10%, i.e., $L_S(LQ) \approx 0.10$. However, such statistical requirements give no guidelines for choosing values of the LQ. The situation is as problematic as for the AQL.

The Structure of MIL-STD-105E

Many national and international attributes sampling standards reproduce the pattern of MIL-STD-105 with minor modifications only. An understanding of MIL-STD-105E is the key to the understanding of many further sampling systems.

MIL-STD-105E as a Sampling System

Schilling [9, p. 277] establishes the following hierarchy: a *sampling scheme* is an indexed collection of sampling plans, including an algorithm for choosing an appropriate plan; a *sampling system* is an indexed collection of sampling schemes, including an algorithm for switching between the schemes. In this sense, MIL-STD-105E is a proper sampling system. In the schemes, the sampling plans are

Table 1 Inspection modes of MIL-STD-105E

Sampling modes	Single, double, seven-stage	OC matched plans No particular advice for selection
Inspection levels	General levels: I, II, III Special levels: S-1, S-2, S-3, S-4	Affect fraction of sample size and lot size. II: regular. I: sample smaller than I, larger risk. III: sample larger than I, smaller risk. S-1, S-2, S-3, S-4: very small samples, large risk.
Inspection states	Normal, tightened, reduced, discontinued	Affect fraction of sample size and acceptance number. Governed by switching rules, see Table 4.

indexed by the lot size N and the AQL. In the system, the subschemes are indexed by the sampling modes, inspection levels and inspection states, see Table 1.

The Contents of MIL-STD-105E

The print version of MIL-STD-105E provides the following materials: (a) information on purpose and scope of the sampling system; (b) basic definitions, in particular of the quality models and quality indices; (c) advice on the implementation and operation of the system, in particular, formation of lots, inspection modes as given by Table 1, sampling technique, switching rules as given by Table 4, algorithm of determining a sampling plan from tables; (d) master tables for determining sampling plans. The first table contains the sample size code letters, see Table 2. The master tables are classified by the sampling mode and by the inspection state. As an example, the master table for **single sampling** under normal inspection is provided by Table 3; (e) Tables of the average outgoing quality limit (*see Rectification Sampling Schemes*), for single sampling under tightened inspection; (f) Tables of the LQ under single sampling if $L_S(LQ) = 0.05$ and if $L_S(LQ) = 0.10$; (g) A table of limit numbers to be used in the rule for switching from normal to reduced inspection, see the rules in Table 4; (h) Average sample number curves (*see Multiple Sampling Plans*) for double and multiple sampling; and (i) The OC curves for the sampling plans under all sample size code letters. The binomial OC is used for inspection for lot proportion nonconforming, and the Poisson OC is used for inspection for lot average number of defects (*see Single Sampling by Attributes and by Variables; Multiple Sampling Plans*).

Table 2 Table of sample size code letters

Lot or batch size	Special inspection levels				General inspection levels		
	S-1	S-2	S-3	S-4	I	II	III
2 to 8	A	A	A	A	A	A	B
9 to 15	A	A	A	A	A	B	C
16 to 25	A	A	B	B	B	C	D
26 to 50	A	B	B	C	C	D	E
51 to 90	B	B	C	C	C	E	F
91 to 150	B	B	C	D	D	F	G
151 to 280	B	C	D	E	E	G	H
281 to 500	B	C	D	E	F	H	J
501 to 1200	C	C	E	F	G	J	K
1201 to 3200	C	D	E	G	H	K	L
3201 to 10000	C	D	F	G	J	L	M
10001 to 35000	C	D	F	H	K	M	N
35001 to 150000	D	E	G	J	L	N	P
150001 to 500000	D	E	G	J	M	P	Q
500001 and over	D	E	H	K	N	Q	R

The Implementation and Operation of MIL-STD-105E

The implementation of MIL-STD-105E requires three subsequent decisions which are associated with different functions of a company.

1. Select one of the 26 AQL values ranging from 0.01% up to 1000%, see Table 3. Values larger than 10% are intended for inspection for the average number of defects (nonconformities) per item. The selection of the AQL value is essentially a business management task. The choice of a threshold for tolerable process quality requires a review and synthesis of all relevant aspects of technical, engineering, contractual, and economic aspects.

Table 3 Master table of single sampling plans (n, c) under normal inspection. Acceptance number $c = Ac$, rejection number $c + 1 = Re$. Down arrows prescribe first sampling plan below arrow, up arrows prescribe first sampling plan above arrow

Sample size code letter	Sample size	Acceptable quality level (normal inspection)															
		0.010	0.015	0.025	0.040	0.065	0.10	0.15	0.25	0.40	...	250	400	650	1000		
		Ac	Re	Ac	Re	Ac	Re	Ac	Re	Ac	Re	Ac	Re	Ac	Re	Ac	Re
A	2											10	11	14	15	21	22
B	3											14	15	21	22	30	31
C	5											21	22	30	31	44	45
D	8											30	31	44	45	↑	
E	13											44	45	↑			
F	20											↑					
G	32											0	1				
H	50											0	1				
J	80											↑					
K	125											↑					
L	200											1	2				
M	315											1	2				
N	500											2	3				
P	800											3	4				
Q	1250	0	1	↑	↓	1	2	3	4	5	6	7	8	10	11		
R	2000	↑		1	2	3	4	5	6	7	8	10	11	14	15		

Table 4 Switching algorithm of MIL-STD-105E

Start	Normal inspection
Normal ↓ tightened Tightened ↓ normal Tightened ↓ discontinued	2 out of 5 preceding lots have been rejected. 5 preceding lots have been accepted. In a tightened inspection series, a total of 5 lots is rejected. All of the conditions (a), (b), (c), (d) are satisfied: (a) 10 preceding lots on normal inspection, none rejected. (b) The total $t_{\Sigma} = t_1 + \dots + t_{10}$ of the sample statistics in 10 preceding samples satisfies $t_{\Sigma} \leq l$ where the limit number l is displayed by Table VIII [1, p. 32] as a function of the AQL and the total number n_{Σ} of sampled units in 10 preceding samples. (c) Production is at a steady state. (d) The authority responsible for sampling accepts reduced inspection. At least one of the conditions (a), (b), (c), (d) is satisfied: (a) A lot is rejected. (b) An inspection result terminates with $Ac < t < Re$, i.e., neither acceptance nor rejection is warranted. (c) Production is irregular or delayed. (d) Other conditions warrant that normal inspection shall be instituted.
Normal ↓ reduced	
Reduced ↓ normal	

2. Select the inspection level from I, II, III, S-1, S-2, S-3, S-4, and the sampling mode (single, double or multiple sampling). This step pertains to the **quality control** department and requires economic, organizational, and statistical expertise.
3. When the choices (1) and (2) are made, the selection of the inspection state and of the specific sampling plan is determined by the operational regime of MIL-STD-105E. This administrative phase is executed by the inspection force according to the following algorithm. (a) Determine the inspection state from the switching algorithm given by Table 4. (b) Determine the lot size N . (c) Use N and the inspection level to determine the sample size code letter X from Table 3. (d) Go to the relevant master table of sampling plans which is identified by the sampling mode and inspection state, see Table 3, for instance. In the table, identify the line with code letter X. In this line, find the sampling plan in the column labeled by the respective value of the AQL.

The Design of MIL-STD-105E

The structure of MIL-STD-105 dates back to sampling schemes developed for the US army from 1942 until 1945, *see Sampling in Industrial Standards* for a detailed historical analysis. Proceeding under wartime conditions the development was strongly oriented by pragmatic criteria. The sampling tables should be rapidly available, simply structured, convenient in implementation and operation. As a consequence, the design of MIL-STD-105 is not built on rigid and consistent theory, but on convenience principles, intuitive plausibility, and rules of thumb. We review the main results of the detailed and profound analysis of the design MIL-STD-105 by Hald [10, pp. 81–99].

Relation between Lot Size and Sample Size. Hald [10, p. 83] states that “there is no theoretical foundation between lot size and sample size in Mil. Std.” The relation was chosen on grounds of intuitive reasoning by the group which constructed the AQL sampling tables for the US army in 1942. A numerical comparison of sample size n_{II} and lot

size N for single sampling in inspection level II at normal inspection shows that $n_{II}/\sqrt{N}$ is approximately constant.

The sample sizes n_I and n_{III} for levels I and III are approximately $n_I \approx 0.4n_{II}$, $n_{III} \approx 1.6n_{II}$. The relation n_{S-i}/n_{II} for the sample sizes under the special inspection levels S-1, S-2, S-3, S-4 is decreasing in N . For largest lot size $N \geq 500\,000$ the maximum sample sizes are $n_{S-1} = 8$, $n_{S-2} = 13$, $n_{S-3} = 50$, $n_{S-4} = 125$, only. The inspection levels S-1, S-2, S-3, S-4 are intended for cases “where relatively small sample sizes are necessary and large sampling risk can or must be tolerated” [1, p. 7], e.g., in case of destructive inspection.

Range of Tabulated AQL Values. The 26 tabulated AQL values in the master tables are obtained by rounding from a geometric series $0.010 \cdot 10^{i/5}$, $i = 0, \dots, 25$. There is no deeper meaning behind this rule except that it seemed plausible to the group of experts which designed the scheme for the US army in the 1940s. MIL-STD-105E [1, p. 1] admits that the range is “not suitable for applications where quality level in the defective parts per million range can be realized”.

Relation between Sample Size and Acceptance Number. We restrict attention to single sampling, see the analysis of double and multiple sampling below. First, consider normal inspection. Analogously to the tabulation of the AQL values, the 15 tabulated values of the sample size n are obtained by rounding from a geometric series $2 \cdot 10^{i/5}$, $i = 0, \dots, 14$. Hence, in the master tables the products $n \times \text{AQL}$ are approximately constant on all left-bottom to right-top diagonals, see Table 3. Correspondingly, the acceptance numbers are fixed on these diagonals such that the OC values $L_S(\text{AQL})$ are also approximately fixed. However, this property is arbitrary and has no systematic motivation. The OC values $L_S(\text{AQL})$ should rather be fixed in the columns, i.e., for fixed quality threshold AQL the probability of acceptance at the threshold should also remain invariant. However, Hald [10, p. 85] demonstrates that in the columns for fixed AQL throughout $L_S(\text{AQL})$ increases from 0.882 to 0.986.

Tightened inspection generally prescribes smaller acceptance number at the same sample size. The acceptance number is determined so that the average outgoing quality limit (AOQL, see **Rectification**

Sampling Schemes) equals the AQL, see [10, p. 87]. This principle is meaningful only under rectifying inspection (see **Rectification Sampling Schemes**).

Single sampling plans are usually defined as a pair (n, c) of sample size n and acceptance number c (see **Single Sampling by Attributes and by Variables**). The master tables of MIL-STD-105E give both the acceptance number $c = \text{Ac}$ and the rejection number Re . Normal and tightened inspection assume $\text{Re} = c + 1$ as usual, i.e., the procedure terminates with acceptance and rejection. Reduced inspection assumes $\text{Ac} + 1 < \text{Re}$ so that the component (b) of the switching rule “reduced $\rightarrow$ normal”, Table 4, can take effect.

The Switching Rules. Hald [10, pp. 88–96] demonstrates the following properties of rules for switching from normal to tightened.

1. Consider a series of lots of constant proportion nonconforming p and constant size N . Then (a) the probability $p_T(p, N)$ of being on tightened inspection is a rapidly increasing function of p , (b) the probability $p_T(p, N)$ of being on tightened inspection is a decreasing function of N .
2. The probability of acceptance under normal inspection strongly exceeds the probability of acceptance under tightened inspection. Whereas the properties (a) and (2) are reasonable to exert pressure on the supplier, property (b) appears strange.

Double and Multiple Sampling Plans. The theory of multiple sampling is described by **Multiple Sampling Plans**. For each single sampling plan $S_{\text{single}} = (n, c)$ with acceptance number $c = \text{Ac} > 0$, MIL-STD-105E provides a double sampling plan S_{double} and a seven-stage sampling plan $S_{\text{seven-stage}}$ such that the sampling plans are approximately OC matched, i.e., $L_{S_{\text{single}}}(p) \approx L_{S_{\text{double}}}(p) \approx L_{S_{\text{seven-stage}}}(p)$.

Differences between MIL-STD-105E and ISO 2859-1

Because of the strong similarity of the standards, ISO 2859-1 can easily be understood by analyzing the few differences from MIL-STD-105E. Essentially the same differences hold between MIL-STD-105E and American National Standards Institute/American Society for Quality Control ANSI/ASQC Z1.4.

1. In the quality model, MIL-STD-105E uses the terms “defective” and “defect” whereas ISO 2859-1 uses the terms “nonconforming” and “nonconformity”.
 2. The term AQL is expanded as acceptable quality *level* in MIL-STD-105E, and as acceptable quality *limit* in ISO 2859-1.
 3. The gaps $Ac + 1 < Re$ between acceptance and rejection number under reduced inspection are given up such that $Ac + 1 = Re$ for all single sampling plans. Component (b) of the switching rule “reduced $\rightarrow$ normal”, Table 4, is eliminated.
 4. The components (a) and (b) of the switching rule “normal $\rightarrow$ reduced”, Table 4, are replaced by the component “The switching score is at least 30”. The sequence $s_1, s_2, \dots$, of switching scores is defined by Table 5.
 5. Double sampling plans in ISO 2859-1 are slightly changed so as reduce the average sample number.
 6. ISO 2859-1 contains tables of the probability $1 - L(AQL)$ of rejecting lots of AQL quality under single sampling. $1 - L(AQL)$ is termed as “*producer’s risk*”.
 7. ISO 2859-1 uses the term “*consumer’s risk quality*” (CRQ) instead of “limiting quality”. The consumer’s risk is fixed at 10%, i.e., $L(CRQ) = 0.10$.
- (b) widely accepted by industry, long-term practical experience;
 - (c) type B focus on the stream of lots;
 - (d) accrued quality experience is used for the choice of sampling plans in a planned and structured way through the switching rules.
- MIL-STD-105E and its derivatives like ISO 2859-1 have the following disadvantages.
- (a) no transparent and consistent design principles, design based on arbitrary reasoning and convenience;
 - (b) vague definition of the AQL, no clear guidelines for choosing AQL values;
 - (c) no foundation in an economic model, no economic evaluation of sampling;
 - (d) no mechanism for conveying prior information on the lot generating process into the design of sampling plans;
 - (e) discontinuation of inspection considered only in the sense of rejection without inspection, not in the sense of acceptance without rejection;
 - (f) design inconsistencies, in particular, considerable variation in the probability of accepting lots of AQL quality, probability of being on tightened inspection strongly decreasing in lot size;
 - (g) the range of AQL values, with a smallest value of 0.01% proportion nonconforming, not inadequate for modern parts per million quality requirements.

Appraisal of MIL-STD-105 and Derivatives

MIL-STD-105E and its derivatives like ISO 2859-1 have the following advantages.

- (a) simplicity, ease in implementation and operation;

Further Parts of ISO 2859

ISO 2859-2 [4], introduced in 1985, provides sampling plans indexed by LQ for isolated lot inspection.

Table 5 Recursive definition of the sequence $s_1, s_2, \dots$, of switching scores at subsequent inspections 1, 2, $\dots$ in ISO 2859-1)

Start	$s_1 = 0$
$s_t \rightarrow s_{t+1}$, single sampling	Let c be the acceptance number at inspection $t + 1$. If $c \geq 2$ and if the lot could be accepted under next smaller AQL: $s_{t+1} = s_t + 3$. If $c \geq 2$ and if the lot could not be accepted under next smaller AQL: $s_{t+1} = 0$. If $c \leq 1$ and if the lot is accepted: $s_{t+1} = s_t + 2$. If $c \leq 1$ and if the lot is not accepted: $s_{t+1} = 0$.
$s_t \rightarrow s_{t+1}$, double sampling	If the lot is accepted after the first sample: $s_{t+1} = s_t + 3$. If the lot is not accepted after the first sample: $s_{t+1} = 0$.
$s_t \rightarrow s_{t+1}$, five-stage sampling	If the lot is accepted after the third sample: $s_{t+1} = s_t + 3$. If the lot is not accepted after the third sample: $s_{t+1} = 0$.

The standard serves as an alternative in situations where the prerequisites of ISO 2859-1, a continuing series of lots and the opportunity to follow the switching regime, are not met. The basic idea is to provide consumer protection by imposing an upper limit on the CR, i.e., the probability $L_S(LQ)$ of accepting a lot of proportion nonconforming LQ. Except for the absence of the switching regime, the structure of ISO 2859-1 is analogous ISO 2859-1. The tabulated lot size ranges match those in ISO 2859-1. The suggested LQ values follow a geometric progression of ten values ranging from 0.5% to 32%. The design of the sampling plans is such that the CR is nominally around the value of 10%, i.e., $L_S(LQ) \approx 0.10$, but usually less. Detailed tables and graphs are provided giving OCs of the sampling plans and their relationship to those in ISO 2859-1, where applicable.

ISO 2859-3 [5], introduced in 1991, contains generic **skip-lot sampling** procedures. Skip-lot sampling procedures are designed to be used as an alternative to reduced inspection under the schemes in ISO 2859-1 where the production quality is high and there is confidence in the supplier's quality assurance system. The procedure involves determining randomly with a specified probability whether a lot presented for inspection will be accepted without inspection. See **Skip Lot and Chain Sampling** for more information on skip-lot procedures.

ISO 2859-4 [6] establishes sampling plans and procedures that can be used to assess whether the quality level of an entity (lot, process, and so on) conforms to a declared value. The sampling plans are designed to provide a risk of less than 5% of contradicting a correct declared quality level, with a 10% risk of failing to contradict an incorrect declared quality level that is related to the limiting quality ratio. Sampling plans are provided corresponding to three levels of discriminatory ability. These procedures are designed primarily for audit purposes and can be used when the quantity of interest is the number or fraction of nonconforming items, or the number of nonconformities, or the number of nonconformities per item.

ISO 2859-5 [7] contains **sequential sampling** schemes that supplement those in ISO 2859-1.

ISO 2859-10 [8] provides a general introduction to acceptance sampling by attributes and a brief

summary of the **attribute sampling** schemes and plans used in ISO 2859-1 through ISO 2859-5. It also provides guidance on the selection of the appropriate inspection system for use in a particular situation.

Variables Sampling Schemes in International Standards

Introduction

Issued in 1957, Military Standard 414 (MIL-STD-414) [1] was the first industrial standard on variables sampling, originally compatible with the attributes sampling standard MIL-STD-105A. Whereas the attributes sampling standard MIL-STD-105 evolved through several versions A, B, C, D, and E, MIL-STD-414 remained unchanged, except for the correction of two typos in 1968, and the compatibility between MIL-STD-105 and MIL-STD-414 was lost. The compatibility was restored by the civilian counterpart ANSI/ASQ Z1.9 whose latest version [2] issued in 2003 is compatible with MIL-STD-105E. The U.S. military cancelled MIL-STD-414 by a note in February 1999 and recommended the use of American National Standards Institute (ANSI)/ASQ Z1.9. For more historical background on industrial sampling standards (*see Sampling in Industrial Standards*).

On the international level, the International Standards Organization (ISO) introduced in 1989 the first variables sampling standard ISO 3951, compatible with the attributes sampling standard ISO 2859, which is a civilian counterpart of MIL-STD-105E. Like ISO 2859, ISO 3951 evolved into a multipart series. The most recent series issued in 2005 and 2006 contains three parts. ISO 3951-1 [3] is essentially compatible with ISO 2859-1, and in great part similar to ANSI/ASQ Z1.9. ISO 3951-2 [4] is an extension to multiple independent quality characteristics. ISO 3951-5 [5] is a sequential scheme for the inspection of a single quality characteristic. The part numbers are chosen to match ISO 2859 (*see Attributes Sampling Schemes in International Standards*), so some numbers are still unused. The present version

of ISO 3951 has been adopted as a national standard in many countries, e.g., as BS 6002 in the United Kingdom or as DIN ISO 3951 in Germany. Since no substantial up-to-date alternatives to the ISO standard exist in industrial variables sampling, the article concentrates on ISO 3951, with particular emphasis on ISO 3951-1 and on ISO 3951-2.

Basics of ISO 3951

Three issues are essential for statistical **product inspection** (SPI): the quality model, the control objective, and the quality indices used. ISO 3951 differs from the attributes sampling standards discussed by **Attributes Sampling Schemes in International Standards** in the quality model only. The control objectives and the quality indices are exactly the same.

The Quality Model of Variables Sampling

Variables sampling schemes are based on the *specification range* quality model (*see Sampling Inspection of Products; Single Sampling by Attributes and by Variables*). A conforming–nonconforming item quality indicator is built from a continuous measurement characteristic like weight, length, volume, by prescribing *specification limits* L and U for the measurement X . The model is explained by Table 1.

ISO 3951 is exclusively designed for the case of a continuous item characteristic X with **normal distribution** $N(\mu, \sigma^2)$, see [3, p. 2]. In the latter case, the process proportion nonconforming p is a function of the process mean μ , and the process standard deviation σ (*see Single Sampling by Attributes and by Variables*). Both the cases of known and unknown standard deviation σ are considered by ISO 3951: operating ISO 3951-1 under known process variance is called “ σ ” method, operating ISO 3951-1 under unknown process variance is called “ s ” method; see the classification of inspection modes in Table 2. ISO 3951-1 [3, p. 12] recommends that the inspection

Table 1 Quality models of variables sampling, based on a continuous measurement X

Specification limits	Item conforming iff	Process proportion nonconforming p
One-sided upper U	$X \leq U$	$p = p_U = P(X > U)$
One-sided lower L	$X \geq L$	$p = p_L = P(X < L)$
Two-sided $L < U$	$L \leq X \leq U$	$p = p_{L,U} = p_L + p_U = P(X < L) + P(X > U)$

2 Variables Sampling Schemes in International Standards

Table 2 Inspection modes of ISO 3951-1

Inspection method	“s” method, “σ” method	Prior knowledge on the process variance σ^2 : σ^2 unknown $\rightarrow$ “s” method σ^2 known $\rightarrow$ “σ” method
Inspection levels	General levels: I, II, III Special levels: S-1, S-2, S-3, S-4	Affect fraction of sample size and lot size II: regular. I: sample smaller than II, larger risk III: sample larger than II, smaller risk. S-1, S-2, S-3, S-4: very small samples, large risk.
Inspection states	normal, tightened, reduced, discontinued	Affect fraction of sample size and acceptance number. Governed by switching rules (see Table 5).

process starts operating with the “s” method where σ is estimated from each sample by the sample standard deviation s (see Table 3). If variability is under control, and a reliable long-term estimate of σ exists, one may switch to the “σ” method, which relies on the estimate as the true value of σ (see Table 3). The **estimation** of σ is explained by the International Organization for Standardization (p. 77. ISO 3951-1 [3]); p. 12, recommends to continue calculating sample standard deviations “for record purposes and to keep the **control charts** up-to-date”. The “σ” method allows for smaller sample sizes than the “s” method.

The classification of the parameters p , μ , σ^2 differs between MIL-STD-414 and ISO 3951. MIL-STD-414 defines the parameters as lot parameters. This view is inconsistent with the type B control objective of the standard, and leads to principal problems in the interpretation of variables sampling (see the discussion in **Single Sampling by**

Attributes and by Variables). ISO 3951 consistently defines p , μ , σ^2 as parameters of the lot generating process.

The Control Objective

As for the attributes sampling standards discussed by **Attributes Sampling Schemes in International Standards**, the control objective of ISO 3951 is of type B, i.e., directed toward “a continuing series of lots of discrete products, all supplied by one producer using one production process” [3, p. 1]. The lot generating production process should be “stable (under statistical control)” [3, p. 1]. The basic tool of type B control are the *switching rules* by which ISO 3951 intends to provide “automatic protection to the consumer should a deterioration in quality be detected” and “an incentive to reduce inspection costs should consistently good quality be achieved” [3, p. 1].

Table 3 ISO 3951-1 decision rules of a sampling plan (n, k) with sample measurements $X_1, \dots, X_n$

“s” method (process standard deviation σ unknown)	
Sample statistics	$\bar{X} = \frac{1}{n} \sum_{i=1}^n X_i$, $s = \sqrt{\frac{1}{n-1} \sum_{i=1}^n (X_i - \bar{X})^2}$, $Q_L = \frac{\bar{X}-L}{s}$, $Q_U = \frac{U-\bar{X}}{s}$
Single lower limit L	$Q_L \geq k \Rightarrow$ accept, $Q_L < k \Rightarrow$ reject
Single upper limit U	$Q_U \geq k \Rightarrow$ accept, $Q_U < k \Rightarrow$ reject
Double limits $L < U$	ISO 3951-1 [3, pp. 18–25]
“σ” method (process standard deviation σ known)	
Sample statistics	$\bar{X} = \frac{1}{n} \sum_{i=1}^n X_i$, $Q_L = \frac{\bar{X}-L}{\sigma}$, $Q_U = \frac{U-\bar{X}}{\sigma}$
Single lower limit L	$Q_L \geq k \Rightarrow$ accept, $Q_L < k \Rightarrow$ reject
Single upper limit U	$Q_U \geq k \Rightarrow$ accept, $Q_U < k \Rightarrow$ reject
Double limits $L < U$	1. Determine f_σ from Table 6, ISO 3951-1 [3, p. 43] (see Table 6) 2. Calculate $\text{MPSD} = (U - L)f_\sigma$ 3. $\sigma > \text{MPSD}$: process variability unacceptable, discontinue inspection 4. $\sigma \leq \text{MPSD}$: accept, if $Q_L \geq k$ and $Q_U \geq k$; otherwise reject

ISO 3951-1 [3, pp. 10–11] permits type A inspection of isolated lots as a secondary control objective. The usefulness of this approach is dubious. There are principal reservations against variables sampling in a type A sense (*see* the discussion in **Single Sampling by Attributes and by Variables**).

Quality Indices: AQL and LQ

The quality indices of ISO 3951 and their definitions are the same as for ISO 2859: the AQL (*acceptance quality limit*), and the LQ (*limiting quality*). The AQL and the LQ are analyzed by **Attributes Sampling Schemes in International Standards**. In the master tables, the 16 AQL values range from 0.01 up to 10.0% (see Table 4). This is exactly that part of AQL values in MIL-STD-105 E and ISO 2859-1 intended for inspection for the proportion nonconforming.

Choice between Variables and Attributes Sampling

The specification range model explained by Table 1 can also serve as basis for the application of an attributes sampling standard as described by **Attributes Sampling Schemes in International Standards**. ISO 3951-1 [3, pp. 11–12], gives some guidelines for the choice between attributes and variables sampling.

Issues listed in favor of variables sampling: (a) Variables sampling is more informative since the underlying measurements X are recorded, and not only the binary conforming-nonconforming indicator. (b) Variables sampling enables smaller sample sizes for OC (operating characteristic) matched sampling plans, i.e., sampling plans which have approximately the same OC function. To illustrate this effect, ISO 3951-1 [3, p. 33] contains a table of OC matched sample sizes. (c) Variables sampling can easily be coordinated with control charts for continuous measurements.

Issues listed in favor of attributes sampling: (a) The implementation of attributes sampling is much simpler. (b) The quality model of variables sampling in the standards is restricted to at least approximately normally distributed continuous measurements X . The methods are inappropriate for skewed distributions of X . (c) Variables sampling has apparent peculiarities which may irritate the user, e.g., rejection based on a sample without nonconforming items.

The issue (c) is most serious. **Single Sampling by Attributes and by Variables** discusses inconsistencies of variables sampling in more detail. Particular inconsistencies are provoked by a type A view of variables sampling for the inspection of single isolated lots.

The structures of ISO 2859-1 and ISO 3951-1 are synchronized. Thus it is possible to start the inspection process under attributes sampling by ISO 2859-1, and to switch to variables sampling under ISO 3951-1 at a later stage when the necessary requirements, in particular approximately normally distributed measurements X , can be confirmed.

The Structure of ISO 3951-1

The structure of ISO 3951-1 is very similar to the structure of ISO 2859-1 which is analyzed by **Attributes Sampling Schemes in International Standards**.

ISO 3951-1 as a Sampling System

The hierarchy of sampling plans, sampling schemes, and sampling systems is discussed by **Attributes Sampling Schemes in International Standards**. Like ISO 2859-1, ISO 3951-1 is a sampling system with various inspection modes and guidelines or rules for choosing or switching between the modes. The inspection modes of ISO 3951-1 are explained by Table 2. Different from ISO 2859-1, ISO 3951-1 contains **single sampling** plans only.

The Contents of ISO 3951-1

The material provided by the print version of ISO 3951-1 can be classified into four parts. (a) sections 1 through 8: statements of purpose, definitions, general Explanations; (b) section 9 until 22, p. 31: advice on implementation and operation; (c) p. 32 until p. 75: tables and graphs; (d) p. 76 until end: normative and informative annexes.

To a considerable degree, the tables in parts (c) and (d) of ISO 3951-1 correspond to tables in ISO 2859-1. The table of sample-size code letters [3, p. 32.] is exactly the same as in ISO 2859-1. The master tables on pages 34 through 42 [3] are arranged in a way analogous to the master tables of ISO 2859-1. The tables are classified by the inspection state (normal,

Table 4 Master table of single sampling plans (n, k) for “s” method under normal inspection. Down arrows prescribe first sampling plan below arrow, up arrows prescribe first sampling plan above arrow

Sample size code letter	Sample size	Acceptance quality limit (% nonconforming)															
		0.010	0.015	0.025	0.040	0.065	0.10	0.15	0.25	0.40	0.65	1.0	1.5	2.5	4.0	6.5	10.0
		k	k	k	k	k	k	k	k	k	k	k	k	k	k	k	k

P	160	↓	3.179	3.082	2.973	2.865	2.733	2.574	2.597	2.447	2.209	2.083	1.921	↑			
Q	200	3.310	3.215	3.109	3.004	2.877	2.747	2.603	2.495	2.377	2.258	2.106	↑				
R	250	3.350	3.247	3.146	3.023	2.898	2.760	2.657	2.545	2.432	2.289	↑					

tightened, reduced) and the inspection method (“s” method, “ σ ” method). As an example, consider the master table for normal inspection under the “s” method displayed by Table 4.

The Implementation and Operation of ISO 3951-1

The implementation of ISO 3951-1 requires five subsequent decisions.

1. Opting for variables sampling instead of for attributes sampling. See the comparison of variables and attributes sampling, above.
2. Choosing between the “s” method and the “ σ ” method. See the discussion of this choice within the framework of the quality model, above.
3. Selecting the AQL value. The choice of a threshold for tolerable process quality is essentially a business management task which requires a review and synthesis of all relevant aspects of technical, engineering, contractual, and economic aspects. The choice is hampered by the vagueness in the definition of the AQL (see the discussion in **Attributes Sampling Schemes in International Standards**).
4. Choosing among the inspection levels S-1, S-2, S-3, S-4 (special), I, II, III (general). As for MIL-STD-105E and ISO 2859-1, the inspection levels affect the sample sizes which is smallest for level S-1, and grows until level III. ISO 3951-1 [3, p. 13] suggests the use of level II “unless special circumstances indicate that another level is more appropriate”.

When the choices 1 through 4 have been made, the further steps – selection of the inspection severity state, of the specific sampling plan (n, k) , and the

operation of (n, k) – are uniquely determined by the operational regime of ISO 3951-1 according to the following algorithm. (a) Determine the inspection state from the switching algorithm (see Table 5). (b) Determine the lot size N . (c) Use N and the inspection level to determine the sample-size code letter X from the respective code letter table (see **Attributes Sampling Schemes in International Standards**). (d) Go to the relevant master table of sampling plans which is identified by the sampling mode and inspection state (see Table 4, for instance). In the table, identify the line with code letter X . In this line, find the sampling plan (n, k) in the column labeled by the respective value of the AQL. The 16 AQL values range from 0.01 up to 10.0%. (e) Operate the sampling plan (n, k) according to the algorithm explained by Table 3. The “s” method with double limits is rather involved, the reader is referred directly to ISO 3951-1 [3, pp. 18–25].

In case of double limits $L < U$, the algorithm contains a test on the process standard deviation, (see Table 3). If the process standard deviation σ is too large with respect to the length $U - L$ of the specification range, sampling cannot find out whether the process mean is inadequately positioned or not. In this case, inspection has to be discontinued until the process variability is reduced to a tolerable degree (see Table 6).

Supporting Procedures

The procedures of ISO 3951-1 are based on assumptions on the measurements X : normality, process variance stability, and, for the “ σ ” method, full knowledge of the process variance. These assumptions should be checked continuously when lots are submitted for inspection. ISO 3951-1 [3, p. 29] recommends

Table 5 Switching algorithm of ISO 3951-1. The rules “normal $\rightarrow$ tightened”, “tightened $\rightarrow$ normal”, “tightened $\rightarrow$ discontinued” are the same as in ISO 2859-1 (see **Attributes Sampling Schemes in International Standards**)

Normal	All of the conditions 1, 2, 3, 4 are satisfied:
↓	1. Ten preceding lots on normal inspection, none rejected
Reduced	2. Ten preceding lots would have been accepted under next smaller AQL
	3. Production is in statistical control
	4. The responsible authority accepts reduced inspection
Reduced	At least one of the conditions 1, 2, 3, 4 is satisfied:
↓	1. A lot is rejected
Normal	2. Production is irregular or delayed
	3. The responsible authority prefers normal inspection

6 Variables Sampling Schemes in International Standards

Table 6 Values f_σ for inspection under double specification limits in the “ σ ” method

Acceptance quality limit (% nonconforming)															
0.010	0.015	0.025	0.040	0.065	0.10	0.15	0.25	0.40	0.65	1.0	1.5	2.5	4.0	6.5	10.0
0.125	0.129	0.132	0.137	0.141	0.147	0.152	0.157	0.165	0.174	0.184	0.194	0.206	0.223	0.243	0.271

Table 7 Control states of ISO 3951-2

Single control	Only a single limit L or U considered, one AQL imposed on p_L or p_U , respectively
Combined control	Double limits $L < U$, same impact of $X < L$ and $X > U$, AQL imposed on $p_{L,U}$
Separate control	Double limits $L < U$, different impact of $X < L$ and $X > U$, AQL _{L} imposed on p_L , AQL _{U} imposed on p_U
Complex control	1. Double-lower: double limits $L < U$, different impact of $X \notin [L; U]$ and $X < L$, AQL _{L,U} imposed on $p_{L,U}$, AQL _{L} imposed on p_L 2. Double-upper: double limits $L < U$, different impact of $X \notin [L; U]$ and $X > U$, AQL _{L,U} imposed on $p_{L,U}$, AQL _{U} imposed on p_U

that control charts of the statistics $\bar{X}$ and s be kept. Additionally, one may keep histograms of the sample measurements to check the assumption of normality.

The Design of ISO 3951-1

The design of ISO 3951-1 replicates the design of ISO 2859-1. The analysis of the design of ISO 2859-1 in **Attributes Sampling Schemes in International Standards** applies implicitly to ISO 3951-1.

A Survey of ISO 3951-2

ISO 3951-2 as an Extension of ISO 3951-1

ISO 3951-2 is an extension of ISO 3951-1. The material and procedures of ISO 3951-1 are a proper subset of the material and procedures of ISO 3951-2. There are three major extensions. (a) Quality model: An arbitrary number $m \geq 1$ of independent continuous quality characteristic is admitted, i.e., on each item m independent measurements $X^{(1)}, \dots, X^{(m)}$ may be taken. Separate specification limits and specification ranges are associated with each of the m quality characteristics. (b) Control model: In the case of double

limits $L < U$, the option of different impacts of nonconformity by an excess below the lower limit L and of nonconformity by an excess over the upper limit U . This leads to four control states of *single*, *combined*, *separate*, and *complex control* as explained by Table 7. Each of the four control states can hold for each of m quality characteristics. (c) Sampling plan and decision algorithm: ISO 3951-2 contains the sampling plans (n, k) of ISO 3951-1 and the corresponding decision rule, see Table 3, for a single quality characteristic under single or combined control as the so-called “form k acceptability criterion”. For multiple quality characteristics and/or separate or complex control, ISO 3951-2 contains sampling plans (n, p^*) as the “form p^* acceptability criterion”.

The Implementation and Operation of ISO 3951-1.

To a large extent, the implementation and operation of ISO 3951-2 and ISO 3951-1 are the same (see the explanations above). The following extensions of the steps 1 through 4 are necessary. Step 2.: Choose between “ s ” and “ σ ” method for each of m quality characteristics separately. Step 3. For each quality characteristic with double specification limits, choose the appropriate control model from

Table 7, and select the corresponding AQL values. For each quality characteristic, the inspection level, the inspection severity state, and the table of sample-size code letters is handled as in ISO 3951-1.

The most important differences of ISO 3951-1 and ISO 3951-2 arise after the basic choices 1 through 4, while operating the master tables and the sampling plan, as it is necessary to handle multiple quality characteristics and the four control states from Table 7. The algorithm proceeds in the following steps 1 through 7.

1. Assign each quality characteristic $l \in \{1, \dots, m\}$ to one of the four control states $C_1, \dots, C_4$.
2. Specify the set $p_{0,1}, \dots, p_{0,r}$ of AQLs which are imposed to the quality characteristics.
3. Associated with the $p_{0,1}, \dots, p_{0,r}$, form r AQL classes $A_1, \dots, A_r$ of quality characteristic indices in the following way: (a) each characteristic $l \in C_1$ (single control) is put into the AQL class A_i associated with the imposed AQL $p_{0,i}$; (b) each characteristic $l \in C_2$ (combined control) is put into the AQL class A_i associated with the imposed AQL $p_{0,i}$; (c) each characteristic $l \in C_3$ (separate control) is put into the two AQL classes A_i, A_j associated with the AQL $p_{0,i}$ imposed on p_L and the AQL $p_{0,j}$ imposed on p_U ; (d) each characteristic $l \in C_4$ (combined control) is put into the two AQL classes A_i, A_j associated with the AQL $p_{0,i}$ imposed on $p_{L,U}$ and the AQL $p_{0,j}$ imposed on p_L or p_U , respectively.
4. From the p^* acceptability criterion master table identified by the inspection severity state, find the *acceptability value* p_i^* for each AQL $p_{0,1}, \dots, p_{0,r}$. The master tables are essentially organized like Table 4 where k is replaced by p^* .
5. For each class A_i and each $l \in A_i$ calculate an estimator $\hat{p}_{l,i}$ of the relevant probability nonconforming. The estimator differs for “s” method and “σ” method.
6. For each class A_i calculate $\hat{p}_i = 1 - \prod_{l \in A_i} (1 - \hat{p}_{l,i})$.
7. If all $\hat{p}_i \leq p_i^*$, accept, otherwise, reject.

ISO 3951-2 lacks a precise guideline on the relation of sampling and quality characteristics. It is unclear whether (a) one sample is taken, and all m quality characteristics are measured on each item in the sample, or whether (b) for each quality characteristic a separate sample is taken. Different

sample sizes for different quality characteristics can occur under the combined “s” and “σ” method where the process standard deviation is unknown for some and known for some other characteristics. Known process standard deviation requires smaller sample size. In this case, under method (a) the measurements would just be cancelled for the “σ” characteristics on some items. The basic orientation should be the requirement of independence of the m quality characteristics. Method (a) is appropriate if the m measurements $X^{(1)}, \dots, X^{(m)}$ taken on one item are independent. If this is not guaranteed, i.e., if the quality characteristics on one item may be correlated, method (b) has to be used.

ISO 3951-5

ISO 3951-5 [5] contains **sequential sampling** schemes that supplement the single sampling schemes provided by ISO 3951-1. The schemes are restricted to the case of known process standard deviation σ .

Rectification Sampling Schemes

Introduction

Acceptance sampling plans usually require corrective action when the lots are rejected. The corrective action can be 100% inspection or screening of rejected lots where all observed nonconforming items are either removed for subsequent rework or returned to the supplier or replaced from a stock of known good items. Such **sampling schemes** are called *rectifying inspection schemes*, because the control activity affects the final product quality after control. Rectifying inspection schemes intend to restrict the long-run proportion nonconforming after control. This intention may be of interest both to the supplier and to the consumer. Thus rectifying inspection schemes are applied in incoming inspection, in-process inspection, or final inspection to give assurance regarding the average quality of material used in the next stage of manufacture or regarding the average quality of final product shipped to consumer.

We consider rectifying inspection for proportion nonconforming under the basic attributes quality model, i.e., items are classified as conforming or nonconforming, lot quality is determined by the lot proportion nonconforming p , and process quality is determined by the process proportion nonconforming $\pi = \bar{p}$. Rectifying inspection under a variables (specification range) quality model can be considered analogously, see [1]. See **Sampling Inspection of Products** for a general exposition of quality models in statistical **product inspection**.

The Dodge–Romig sampling tables [2] are the best-known rectification sampling scheme. The sequential rectification scheme by Anscombe [3] requires less than 100% inspection of rejected lots. In theory, Anscombe’s scheme is more economical, but it is more complicated in implementation. We concentrate on the simple Dodge–Romig scheme. For an exposition of Anscombe’s scheme, the reader is referred to [1].

Several types of rectification procedures exist. The two most important are (a) *replacing procedure*: all nonconforming items discovered in the course of sampling, or, in the case of rejection, by screening the

lot are replaced by conforming items; (b) *removing procedure*: all nonconforming items discovered in the course of sampling, or, in the case of rejection, by screening the lot are removed. The replacing procedure is more common, and is assumed by the Dodge–Romig scheme.

Rectifying inspection can be considered in a type A framework where the decision target is a finite lot of items $1, \dots, N$, or in a type B framework where sampling and decision is directed toward the lot generating process (see **Sampling Inspection of Products** for the distinction of type A and type B procedures). Originally, the Dodge–Romig scheme is decidedly intended for type A inspection as expressed by Dodge and Romig [4]: “The purpose of the inspection is to determine the acceptability of individual lots submitted for inspection, i.e., sorting good lots from bad.” Later, the second edition [2] of the sampling tables distinguishes type A and type B, and considers rectifying inspection in a type B sense for the control of the process output, too. In the sequel we adopt the original type A view.

Performance Measures and Characteristic Quantities

The basic performance measure of any sampling plan S for lot proportion nonconforming is its *operating characteristic* (OC) function, i.e., the probability

$$L_S(p) = P(\text{accept} \mid \text{lot proportion nonconforming} = p) \quad (1)$$

as a function of the actual value p of the lot proportion nonconforming. For double sampling plans, additional important measures are the probabilities

$$A_{S,l}(p) = P(\text{accept in stage } l \mid \text{lot proportion nonconforming} = p) \quad (2)$$

of accepting in stage l , $l = 1, 2$. Under a strict type A view, the OC functions and acceptance probabilities have to be calculated from appropriate hypergeometric probabilities (see **Single Sampling by Attributes and by Variables** for single and **Multiple Sampling Plans** for multiple sampling). The approximation schemes developed by Dodge and Romig [2] are based on approximating the hypergeometric probabilities by suitable Poisson ones in the way indicated

2 Rectification Sampling Schemes

by **Single Sampling by Attributes and by Variables** and **Multiple Sampling Plans**. Dodge and Romig [2] use the exact hypergeometric formulas for the calculations of tables only.

Rectification plans try to control the proportion nonconforming *after* application of the sampling plan, but to this end they incur a potentially high *total* inspection amount. These two contrary aspects are expressed by three specific performance measures, the *average outgoing quality* (AOQ), the *average outgoing quality limit* (AOQL), and the *average total inspection* (ATI). Table 1 explains these performance measures and provides formulas for the AOQ and the ATI under single and double sampling plans. Simple closed formulas for the AOQL exist in special cases only. For AOQ and ATI formulas under multiple and sequential sampling, consider **Multiple Sampling Plans**.

The Dodge–Romig scheme uses two further characteristics: the *lot tolerance percent defective* (LTPD) and the *consumer's risk* (CR). These characteristics are not specific for rectification schemes (see **Sampling Inspection of Products** for an explanation on OC related characteristics).

The Dodge–Romig Designs of Rectification Plans

The Dodge–Romig sampling tables [2] provide two designs for sampling plans: LTPD design and AOQL design. Both designs are based on minimizing the ATI as a function of the sampling plan under a prescribed value of the LTPD or the AOQL, respectively. The

ATI is a clear economic target, whereas the LTPD and the AOQL have no direct economic interpretation. Accordingly, the Dodge–Romig design may be classified as *semieconomic*. The designs are applied to single sampling plans (n, c) and to double sampling plans $(n_1, n_2, a_1, a_2, r_1, r_2)$ with the additional restriction $r_1 = r_2 = a_2 + 1$ (see **Single Sampling by Attributes and by Variables** and **Multiple Sampling Plans** for general expositions on single and multiple sampling plans).

As defined in Table 1, the ATI depends on the unknown lot proportion nonconforming p . Some prior knowledge on the lot proportion nonconforming is required. Dodge and Romig assume the so-called *process average proportion nonconforming* $\bar{p}$ which is defined as the expectation $E[P] = \bar{p}$ of the random lot proportion nonconforming P , see [2, p. 25]. In the lot and process quality model of **Sampling Inspection of Products**, $\bar{p} = \pi$ is the process proportion nonconforming. In a rigorous prior knowledge approach (see **Prior Information in Sampling Schemes** for a survey), one should consider the expected value $E[ATI(P)]$ of the random $ATI(P)$. Instead, Dodge and Romig [2] consider just $ATI(\bar{p})$. Various attempts have been made to justify this approach, in particular, considering $E[ATI(P)] \approx ATI(\bar{p})$ as a sufficiently good approximation under reasonable **prior distributions** of P , or assuming a one-point prior with outliers, see [5, p. 100].

The rationale of sampling inspection under knowledge of the expected proportion nonconforming $\bar{p} = \pi$ in the lot generating process is seriously questioned by the economic analyses of Feigenbaum [6]

Table 1 Characteristic quantities of a rectification sampling plan for lot proportion nonconforming

Generic definitions	
AOQ	Average outgoing quality. The expected value of the lot proportion nonconforming after application of a rectification plan as a function $AOQ(p)$ of the lot proportion nonconforming p before inspection.
AOQL	Average outgoing quality limit. Maximum $p_L = AOQL$ of the AOQ, i.e., $p_L = AOQL = \max_{0 \leq p \leq 1} AOQ(p)$.
ATI	Average total inspection. The expected value of inspected items, including 100% inspection in case of rejection.
Single sampling plan (n, c) with OC $L(p)$	
AOQ(p)	$AOQ(p) = p \left(1 - \frac{n}{N}\right) L(p) = p \frac{N - ATI(p)}{N}$
ATI(p)	$ATI(p) = n + (1 - L(p))(N - n)$
Double sampling plan $(n_1, n_2, a_1, a_2, r_1, r_2)$ with OC $L(p)$ and with probabilities $A_l(p)$ of terminating with acceptance in stage l , $l = 1, 2$	
AOQ(p)	$AOQ(p) = p \left\{ \left(1 - \frac{n_1}{N}\right) A_1(p) + \left(1 - \frac{n_1 + n_2}{N}\right) A_2(p) \right\}$
ATI(p)	$ATI(p) = n_1 A_1(p) + (n_1 + n_2) A_2(p) + N (1 - L(p))$

or Deming [7] (see **Sampling Inspection of Products**). In practice, however, process parameters are never completely stable. Even for a process under statistical control there may be occasional outliers in the process parameters. Protection against the effect of such outliers on product quality is a reasonable motivation for sampling inspection, see the arguments by Hald [5]. It remains to be analyzed, however, whether this motivation justifies the amount of sampling inspection imposed by the Dodge–Romig scheme. Unfortunately, the scheme gives no economic guidelines to answer this question.

The Dodge–Romig LTPD Design

The LTPD is considered as a relatively poor value p_t of p . Lots with $p = p_t$ should rarely be accepted. The Dodge–Romig LTPD design imposes the restriction $L_S(p_t) = 0.10$. From the consumer's perspective, the LTPD can be considered as the *consumer's quality* and the restriction $L_S(p_t) = 0.10$ as imposing a CR of 10% (see **Sampling Inspection of Products**). The Dodge–Romig LTPD plan is defined as the sampling plan S^* , which minimizes $ATI_S(\bar{p})$ among all sampling plans S satisfying $L_S(p_t) = 0.10$.

For the solution of this problem, Dodge and Romig [2] made two contributions: (a) An approximate solution based on approximating the exact hypergeometric acceptance probabilities by a Poisson distribution. See [5] for a detailed description of the derivation. Charts and tables support the implementation of the approximate solution. The algorithm is described by Schilling [8] in detail. (b) Tables of the exact solution based on the exact hypergeometric acceptance probabilities arranged as follows: one separate table for

each of the eight LTPD values 0.5, 1.0, 2.0, 3.0, 4.0, 5.0, 7.0, and 10.0%, where each table is arranged in six intervals for the process average $\bar{p}$ and where the maximum of $\bar{p}$ is half the respective LTPD. For larger process averages, sampling inspection is rather inappropriate compared to rejection without inspection. Lot size ranges from 1 to $N = 100\,000$. To understand the structure of the Dodge–Romig LTPD tables consider Tables 2 and 3, which provide an excerpt of the Dodge–Romig AOQL tables. The LTPD tables are arranged analogously.

Hald [5] analyzes the approximate solution and the tables in detail. The quality of the approximate solution decreases with increasing values of the LTPD p_t and of the fraction $\bar{p}/p_t$. In the tables, larger deviations from the exact solution occur only if the process average is close to the boundaries of the six intervals.

The Dodge–Romig AOQL Design

The essential objective of rectifying inspection is to impose a specified AOQL as an upper bound for the AOQ, i.e. the expected proportion nonconforming after application of the sampling plan. This objective is expressed by the AOQL design. A value $p_L = \text{AOQL}$ is prescribed. The Dodge–Romig AOQL plan is defined as the sampling plan S^* which minimizes $ATI_S(\bar{p})$ among all sampling plans S satisfying $\text{AOQL}_S = p_L$.

Quality cannot be inspected into a product, i.e. sampling plans cannot improve upon the quality provided by the lot generating process. Accordingly, prescribing an AOQL $p_L < \bar{p}$ smaller or equal to the process proportion nonconforming is absurd. If

engineering or economic reasoning suggests a value p_L as a coercive bound for outgoing quality, and if $p_L < \bar{p}$, then lots from the process should be rejected without inspection. Throughout, the AOQL design assumes $p_L \geq \bar{p}$.

For the numerical implementation of the AOQL design [2] restrict attention to approximations of the exact hypergeometric acceptance probabilities by Poisson probabilities. Two contributions are made: (a) A simply calculable approximate solution, see [5] for a detailed description of the derivation. Charts and tables support the implementation of the approximate solution. The algorithm is described by [8] in detail. (b) Tables of the approximate solution arranged as follows: one separate table for each of the 13 AOQL values 0.1, 0.25, 0.5, 0.75, 1.0, 1.5, 2.0, 2.5, 3.0, 4.0, 5.0, 7.0, and 10.0%, where each table is arranged in six intervals for the process average $\bar{p}$ and where the maximum $\bar{p}$ is the respective AOQL. Lot size ranges from 1 to $N = 100\,000$. For illustration, Tables 2 and 3 display an excerpt of the Dodge–Romig AOQL tables for single and double sampling under a prescribed AOQL of 0.1%. Hald [5] analyzes the quality of the approximate solution and of the tables in detail.

Issues in the Implementation of the Dodge–Romig Scheme

The Dodge–Romig scheme is implemented in the following steps:

1. Decide between LTPD and AOQL plans.
2. Specify values of the LTPD or AOQL, respectively.
3. Specify the process average proportion nonconforming.
4. Decide between single and double sampling plans.
5. Determine the sampling plan from tables or from approximation formulas or from software.

The Dodge–Romig system is implemented in several production management packages, e.g. in a package distributed by Rockwell Automation. The final step 5 is simple and can easily be executed by shopfloor practitioners after suitable training. The first four steps have to be discussed.

Decision between LTPD and AOQL Tables

Originally, Dodge and Romig [9], subsumed LTPD plans under lot quality protection, AOQL under average quality protection. This distinction has often been interpreted in the sense that LTPD plans focus on the quality of single lots, whereas AOQL plans focus on the quality of a stream of lots. However, as stated later by Dodge and Romig in their amendments to the second edition of the sampling tables [2], both types may be considered in a type A view (focus on lots) or in a type B view (focus on the process). The different objectives of LTPD and AOQL plans are rather related to the distinction between *submitted*

and *outgoing* product: LTPD plans protect against accepting bad submitted quality, AOQL plans restrict the proportion nonconforming of outgoing product after inspection.

Specifying the LTPD or the AOQL

Both the AOQL and the LTPD are clearly defined from a formal point of view. However, the problem is to make these concepts meaningful and manageable in practice, in particular to relate them to the economy of **quality control**. The Dodge–Romig scheme gives no distinct economic guidelines on how to choose values of the AOQL or LTPD. Dodge and Romig [2, p. 5] recommend to the manufacturer the selection of an AOQL equal to the “acceptable quality level” specified by the consumer. Dodge and Romig [2, p. 6] recommend to “consider and compare the cost of inspection with the economic loss that would ensue if quality as bad as the LTPD were accepted often (or if the *average level* of quality were greater than the AOQL)”. In the end, these advices amount to relate the LTPD and the AOQL to the *break-even quality* in an economic profit–loss model for inspection (*see Sampling Inspection of Products*). However, the Dodge–Romig scheme contains no guidelines to specify such a model.

Specifying the Process Average

For a reasonable **estimation** of $\bar{p}$, knowledge on the process and data from the process are necessary.

- (a) The lot generating process is basically in a state of control, with only occasional out-of-control situations.
- (b) Quality records from the lot generating process exist. The estimation of $\bar{p}$ is not straightforward, since out-of-control outliers have to be excluded from the estimation. Dodge and Romig [2, p. 32] suggest a proportion nonconforming chart procedure:
 1. Plot the proportion nonconforming figures from the last 10 to 25 lots, excluding “nonrepresentative” lots with a strong out-of-control suspect.
 2. Verify a basic state of statistical control by comparing the data with 3σ limits.
 3. Replace points beyond 3σ limits by corresponding 2σ limits.

4. Use the average of the data as an initial estimate of $\bar{p}$.
5. Start the sampling inspection process. Update the initial estimate of $\bar{p}$ successively by using the estimates provided by the samples or screening procedures.

Small changes in the process average will have no effect on the sampling plan, see the efficiency studies by [5]. In particular, the tables provided by [2] (see Tables 2 and 3 above) are organized in intervals of the process average, so that only an excess over the interval boundaries will affect the design. Hald [5, p. 105] recommends that “in case of doubt the process average should be overestimated thus choosing a larger **sample size** than necessary because this leads to a smaller increase in the ATI than an underestimation of the same size.”

Deciding between Single and Double Sampling

The ordinary performance measure of multiple sampling is the average sample number (ASN) (*see Multiple Sampling Plans*). In the Dodge–Romig scheme, under given process average and given LTPD or AOQL, respectively, the ASN of single sampling is not in general smaller than the ASN of double plans. Under some constellations, even the first stage double sample size is larger than the single sampling size (compare Tables 2 and 3). However, for rectifying inspection, the interesting measure is not the expected total *sampling* amount, but the expected total *inspection* amount, i.e. the ATI. Dodge and Romig [2, pp. 30–31] demonstrate that the single sampling ATI consistently exceeds the double sampling ATI. The pattern is exactly the same as for the ASN-based comparison (*see Multiple Sampling Plans*): the advantage of double sampling is greatest for very small process proportion nonconforming. However, Dodge and Romig [2] reasonably attract attention to added costs from the administration of double sampling, naming “interruption of work” and “extra handling of product”.

Appraisal of the Dodge–Romig Scheme

We evaluate the usefulness of the Dodge–Romig scheme in modern industrial quality control. *See Acceptance Sampling in Modern Industrial Environments* for a general description of challenges

for statistical product inspection in modern quality control.

The Dodge–Romig scheme has two virtues, particularly in comparison with the Military Standard: (a) a definite, explicitly stated and transparent design; (b) *via* the process average, a mechanism that conveys previous information on product quality. In particular, a mechanism that reduces sample size in the case of improving product quality.

The following aspects of the Dodge–Romig scheme are unfavorable in a modern quality control environment: (a) the core design parameters LTPD and AOQL are not motivated by an economic model, in particular they are not clearly related to economic break-even qualities; (b) the range of the LTPD and AOQL considered in the tables—smallest LTPD at 0.5%, smallest AOQL at 0.1% – are much too high for modern rigorous product quality requirements; (c) the rationale of sampling under the assumption of a known process quality parameter is not made totally clear. Sampling inspection is not evaluated in comparison to the no sampling alternative.

Continuous Sampling

Introduction

Acceptance sampling procedures are classified into type A and type B, *see Sampling Inspection of Products*. Type A procedures operate on a lot-by-lot basis: Incoming or outgoing lots of product are inspected to decide between accepting or rejecting a lot. This lot-by-lot framework is rather inappropriate if, in a strict type B view, a manufacturing process successively generating items shall be controlled. In this case, two reasons oppose the building of lots from the produced items: (a) Arranging the lots would be costly and time consuming. (b) The decision about the actual process quality would be unduly delayed. For example, if products like personal computers are produced on an assembly line, any disturbance shall be detected quickly. Then it makes no sense to wait for controlling the process until a lot has been built up. In this case, continuous item-by-item sampling plans are more appropriate.

Item-by-item sampling plans for continuous control of production processes were developed by Dodge [1]. The quality of the process is measured by the process nonconformance probability, i.e., by the probability that a manufactured item is nonconforming. A continuous sampling plan (CSP) consists of alternating sequences of screening (100% inspection) and sampling inspection. Details of the operation of CSPs are described subsequently. CSPs are rectifying inspection plans where any nonconforming item is reworked or replaced by a conforming one. Thus, product quality after control is better than before.

Dodge CSP-1 Plan

The CSP-1 plans introduced by Dodge [1] in 1943 are specified by the so-called clearance number i , the sampling frequency f , and the following instruction: start with screening, i.e., inspecting each item produced. As soon as i consecutive items have been found to be conforming, sampling inspection is started, where one out of $k = 1/f$ consecutively produced items is selected and inspected. If a sampled item is found to be nonconforming, revert back to screening. Inspection is rectifying, i.e., all nonconforming items found are either replaced

Figure 1 Operating procedure of CSP-1

by conforming ones or reworked. The operating procedure for CSP-1 is shown in Figure 1.

Properties of CSP-1

The choice of the clearance number i and the sampling fraction f is usually based on practical considerations about the manufacturing process and the required statistical properties of the sampling plan. The statistical properties of CSP-1 are derived in [1] under the assumption that the nonconforming probability of the process is constant and given by p , see also [1, 2].

- The average number of items inspected in a 100% screening sequence following the detection of a nonconforming item is equal to

$$u = \frac{1 - (1 - p)^i}{p(1 - p)^i} \quad (1)$$

- The average number of nonconforming items passing, while sampling inspection is performed, is given by

$$v = \frac{1}{fp} \quad (2)$$

Figure 2 OC curves for the following four cases (from top to bottom): (a) $f = 0.02, i = 100$, (b) $f = 0.08, i = 100$, (c) $f = 0.04, i = 210$, and (d) $f = 0.08, i = 210$

- The average fraction of items (AFI) inspected in the long run is

$$AFI = \frac{u + fv}{u + v} \quad (3)$$

- The average outgoing quality (AOQ) is obtained from equation (3) as

$$AOQ = p(1 - AFI) \quad (4)$$

- The probability of accepting an item produced when using the CSP-1 sampling procedure, is denoted by $L_{i,f}(p)$ and defines the operating characteristic (OC) curve of a continuous sampling plan, CSP-1. It is given by

$$L_{i,f}(p) = \frac{v}{u + v} = \frac{(1 - p)^i}{f + (1 - f)(1 - p)^i} \quad (5)$$

The OC curves for some values of f and i for CSP-1 are displayed in Figure 2. It can be shown that for moderate-to-small values of f , the clearance number i has a larger effect on the shape of the curve than does f .

Derman *et al.* [3] investigates the properties of CSPs without the assumption of a constant nonconformance probability p .

Extensions of CSP-1

Sometimes the detection of a single nonconforming item does not warrant returning to process screening, for example when dealing with minor defects.

To overcome this difficulty, Dodge and Torrey [4], proposed the continuous sampling plans, CSP-2 and CSP-3 as extensions of CSP-1. Under CSP-2, process screening is reinstated only if under sampling inspection two nonconforming items have been found within a sequence of K sample units. It is common practice to choose K equal to the clearance number i . CSP-2 plans are indexed by their average outgoing quality level (AOQL). Note that a given AOQL does not determine the pair (i, f) uniquely, but may be obtained by different combinations of i and f . The continuous sampling plan, CSP-3 is very similar to CSP-2, but it is designed to give some additional protection against spotty production. It requires that after a nonconforming item has been found in sampling inspection, the immediately following next four units in succession should be inspected. If any of these four units is nonconforming, process screening is resumed immediately. If no nonconforming items is found among the inspected four items, the plan continues as under CSP-2. Multilevel CSPs are proposed and analyzed by Liebermann and Solomon [5] and Derman *et al.* [3].

MIL-STD-1253C

MIL-STD-1253C contains five different types of continuous sampling plans: CSP-1, CSP-2, CSP-F (CSP-1 modified for short production runs), CSP-V (CSP-1 with an option to reduce the clearance number), and CSP-T (three level CSP scheme with three levels of the sampling frequency, namely, f , $f/2$, and $f/4$). Tables assist the user in designing a sampling plan.

The sampling plans in MIL-STD-1253C are indexed through the sampling frequency code letter, which is related to the production speed, and the $AOQL$. Additionally, they are also indexed through the acceptable quality level (AQL) of MIL-STD-105E. However, CSP plans are not AQL plans and do not have an AQL value naturally associated with them. CSP plans are designed for situations in which production is continuous and considering lots is not meaningful. Therefore, in MIL-STD-1253C, the sampling plan tables are footnoted and indicate that the AQL values have no meaning relative to the plan, but are only used as an index.

Note that the properties of the plans offered by MIL-STD-1253C assume that the process is in a state of statistical control, i.e., a constant process

nonconformance probability. If this assumption is not met sufficiently well, the sampling plan properties may differ largely from those given in the standard.

Skip Lot and Chain Sampling

Skip-Lot Sampling Plans

The **continuous sampling** plan (CSP-1) aims at controlling the outgoing quality of a continuous production process by inspecting individual items. In [1], Dodge proposed to apply the operation rules of CSP-1 to a continuous flow of lots and called the resulting procedure *skip-lot sampling plan* (SkSP-1). The goal is the same as for the CSPs, namely to quit in certain situations 100% control and, thus, reduce inspection costs. Dodge recommended the use of SkSPs in case that the flow of lots is produced in successive batches by a reliable production process or if the tests to be performed are time consuming and expensive.

The operating procedure for SkSP-1 is the same as for CSP-1 with the only differences that the word “item” has to be replaced by the word “lot” and the demand to “inspect an item” by the somewhat vague demand “test the lot”. The basic relations stated for CSP-1 for individual items hold also in case of SkSP-1 for lots. In [1] a nomogram is given for selecting a SkSP-1 plan guaranteeing a given average outgoing quality limit (AOQL), which is interpreted as the maximum fraction of accepted lots that will be nonconforming, where a lot is called *conforming* if the acceptance criterion of the test is met and otherwise it is called *nonconforming*.

Perry proposed in [2] a SkSP of type SkSP-2, where each lot to be inspected is sampled according to some lot **acceptance sampling** plan the so-called reference plan. Then, SkSP-2 is operated as follows:

1. Start with normal sampling inspection (inspecting every lot), using the reference plan.
2. When i consecutive lots are accepted on normal inspection, switch to skipping inspection (inspect a fraction f , $0 < f < 1$, of the lots).
3. When a lot is rejected on skipping inspection, switch to normal inspection.

Perry [2] derived the operating characteristic (OC) function of a SkSP-2 plan and studied the properties of SkSP-2 plan in terms of the average sample number (ASN), the average outgoing quality (AOQ), and the **average run length** (ARL). Finally, Perry [2]

analyzes the AOQ for a SkSP-2 plan. He defines the AOQ as fraction of outgoing lots that are nonconforming, where a nonconforming lot is one “whose sample fails (or would fail, if inspected) to meet the acceptance criterion of the reference plan”. Perry [3] also developed three different types of two-level SkSPs, which are based on the operating procedures of the multilevel plans (MLPs) for continuous sampling of Lieberman and Solomon [4] and of the tightened MLPs of Guthrie and Johns [5]. A detailed description of SkSP-2 plan and the two-level SkSPs is given in Stephens [6].

There are a number of shortcomings with respect to skip-lot sampling as described in literature. A first one refers to the fact that the properties are derived assuming constant nonconformance probability, a condition, which generally is not met in practice. A second severe weakness is the definition of nonconforming lot, which actually characterizes the reference sampling plan, but does not define the nonacceptability of a lot.

Chain Sampling Plans

The concept of chain sampling was developed by Dodge [7] as an alternative to attribute **single sampling** plans with zero acceptance number. Chain sampling plan (ChSP-1) makes not only use of the result of the actual sample, but also of the results concerning a number of preceding lots. The plan avoids rejection of lot on the basis of one single nonconforming item resulting in a relatively poor discrimination **power** between good and bad quality that marks the zero-acceptance number single sampling plan. The operating procedure of a ChSP-1 is as follows.

- For each lot, select a random sample of size n items and test each unit for conformance with the specifications.
- Accept the lot if d , the observed number of nonconforming items among the n sampled items, is zero; if $d > 1$, reject the lot.
- If the sample contains exactly one nonconforming item ($d = 1$), accept the lot provided there have been no nonconforming unit in the previous i samples of size n .

Dodge [7] proposed to apply chain sampling in circumstances where the successive lots are produced under similar conditions and are inspected in the

2 Skip Lot and Chain Sampling

order of production. Such situations may arise in receiving inspection of continuing supply of purchased materials produced within a manufacturing plant. Chain sampling is also recommended, when the probability of producing a nonconforming item is very small and at the same time large samples are practicable. A ChSP might also be of advantage in cases where the inspection is costly requiring a small **sample size**, i.e., the acceptance number zero.

The advantage of chain sampling over single sampling plans with zero-acceptance number is that the acceptance probability does not drop as rapidly for small values of the nonconformance probability p . A detailed review and a discussion on conditions for applications and measures of performance of the ChSP-1 plan are given in Stephens [6], Schilling [8], and Govindaraju [9]. Dodge [7], and Clark [10] studied the properties of ChSP-1 plans based on the OC curves for various combinations of n and i . Note that the OC curve for ChSPs is determined by considering an infinite series of lots produced with constant nonconformance probability p .

A generalized family of “two-stage” ChSPs, which extend the ChSP-1 plans, was developed by Stephens and Dodge [11] and presented in various technical reports and papers. The generalized two-stage ChSP with different sample sizes in the two stages is denoted by ChSP- $(n_1, n_2; k_1, k_2; c_1, c_2)$. The operating procedure and other properties of the general two-stage ChSP is derived in Dodge and Stephens [12] and Stephens and Dodge [11].

Check Inspection and Demerit Rating Sampling

The check inspection and demerit rating plan was introduced by Dodge and Torrey [13] for processes with a tight **process control** resulting in a high and stable quality level, making lot acceptance sampling by the consumer appear unnecessary. In such a situation check inspection is employed for process quality assurance purposes. The inspection shall be carried out by an inspection agency on the manufacturer’s premises from the customer’s point of view. Samples are selected at random from the completed product allowing to control and to maintain process quality at the desired high level. The product to be tested by check inspection refers generally to items which have a number of components with several quality characteristics.

Because of their complexity products are divided into classes. According to some class properties, the monthly sample size necessary for check inspection is taken from some empirically determined curves (see Dodge [13]) as function of the number of items produced per month. The monthly sample is divided into a number of smaller samples, which must be taken at random from the finished product so as to represent the entire output of the month.

Check inspection is particularly applied to complex products and, therefore, the number of nonconforming items or the number of defects in a sample appears to be not refined enough for reflecting quality. Therefore, a classification scheme for the seriousness of defects is used, where the seriousness is measured by so-called demerits per unit. Four classes of seriousness (Class A, B, C, D) are admitted in [13] with demerit weights of 100, 50, 10, and 1, where a higher weight means a higher seriousness of the defect. Based on the sample and some nonconformance criteria, a number of decisions can be made, which include acceptance, rejection, drawing an additional sample, inspect prior and subsequent product, etc.

Besides the sampling procedure described above, a monthly **control chart** is maintained on the basis of the cumulative number of demerits of the considered classes. This control chart reflects the development of the overall process quality and can be used for making decisions with respect to the process. The control limits are determined by empirical and practical considerations.

The possibilities of rating the seriousness of defects by demerits is investigated in many papers. Dodge [14] was one of the first to address the problem. A more recent investigation of the probability distribution of the considered demerits is given in [15].

The check inspection and demerit rating plans as presented in [13] are a purely heuristic inspection scheme without a theoretical basis. Therefore, it is impossible to make a reliable judgment of its performance in a given situation.

Deming’s (k_1, k_2) “All-or-None” Inspection Policy

For lot inspection Deming [16] stresses the necessity of determining the so-called breakeven quality, which distinguishes lots as being acceptable without inspection from lots which should be accepted only after

100% inspection. For defining the breakeven quality Deming introduces the cost to inspect one item with value k_1 , the cost caused by an accepted nonconforming item with value k_2 and the cost to replace a nonconforming item found during inspection with value k . Assuming $k \approx k_1$ Deming obtains the breakeven quality as the ratio (k_1/k_2) .

Clearly, if the production process has a nonconformance probability smaller than the breakeven quality, it makes sense, at least in the long run, to accept incoming lots without inspection. Similar, if the production process has a nonconformance probability larger than the breakeven quality, 100% inspection of all incoming lots is indicated from the long-run perspective. These two rules are known as *Deming's all-or-none inspection policy*. It assumes that the production process is in a state of statistical control and, moreover, the value of the nonconformance probability is known.

For achieving these two conditions, Deming demands that the process must be continuously observed using control charts on the basis of small samples, preferably in cooperation between supplier and purchaser. This is a similar situation as assumed for Dodge's check inspection and demerit rating plan.

For showing that sampling makes no sense when the process is in a state of statistical control with known quality level p , Deming – following Mood [17] – shows that the random numbers of nonconforming items in a sample and in the remainder, respectively, are uncorrelated, implying that the sample result does not yield any additional knowledge about the quality of the remainders. Thus, drawing a sample makes no sense from an economic point of view. This fact also illustrates the vital importance to reach a state of statistical control for the corresponding process. In order to highlight this demand, Deming [16] characterizes a process not under statistical control as “chaos”.

Deming's (k_1, k_2) inspection rule is important, because it attracts the attention to the questions of breakeven quality, which is widely neglected in the literature on lot acceptance sampling. Moreover, Deming stresses the relation between process distribution and lot distribution and the fact that quality is determined by the process and, therefore, statistical **quality control** should focus on the process.

Deming's all-or-none inspection rule has been investigated in many papers under various circumstances, see for example [18].

Economic Sampling Schemes

Purpose of Sampling

In all areas of the human society, decisions must be made to cope with the uncertain future development. Whether a decision is appropriate or not depends on how well it takes account of the relevant initial conditions at hand, which affect the future development strongly. The main reason why there is uncertainty about the future development is the very fact that the relevant conditions are generally not fully, but only partially known. The overall aim of any industrial organization is to make profit. Therefore, any effort aiming at determining relevant initial conditions must be looked at from an economic viewpoint.

At this point **sampling schemes** come into play. They are used within a decision-making process for improving the knowledge about the relevant initial conditions, e.g., the quality of a lot of products. Such knowledge is indispensable for the decision process to avoid an economic loss by making a decision that is inappropriate in the given situation.

Problems with Sampling

There are two interrelated problems with sampling. The first one results from the fact that sampling costs money and constitutes, therefore, itself an economic loss. The second one is even worse. If sampling leads to false beliefs about the initial conditions, i.e., about the economic situation, then the decision will be wrong, for sure. In such a case the wrong decision incurs a loss, which is increased by the sampling cost. The relation between these two problems lies in the relation between sampling error and sampling cost: decreasing the probability of a wrong sampling result requires an increase in the **sample size** which leads to an increase in the sampling cost.

These considerations show that sampling is closely related to the cost situation and that any sampling plan not resulting in an increased economic yield should be called inappropriate. Therefore, selecting a sampling scheme for application without considering the given economic situation is hazardous and leads almost necessarily to an avoidable economic loss.

State of Economic Sampling Schemes

Economic sampling schemes, i.e., sampling schemes based on a thorough analysis of the economic impact of decisions and sampling cost, are more or less unknown in industry. There are several reasons for this surprising fact.

- There are no national or international standards for economic sampling schemes.
- Most of the existing economic sampling schemes are unattractive, because they are too complicated and are often based on unrealistic assumptions.
- Finally, selecting an appropriate economic sampling plan would necessitate a close cooperation including the exchange of relevant data by different departments of an organization. Such a cooperation is often not possible.

The first-mentioned point is explained by the origin of the existing national and international standards for sampling schemes in U.S. military standards, which were developed independently of any economic considerations. By adopting the military approach, the national and international organizations for standardization abandoned any opportunity for developing more target oriented, i.e., economic sampling schemes.

In statistical **quality control**, economic sampling schemes were first discussed and investigated in the realm of Bayes statistics, which required the specification of a prior probability distribution of the quality characteristic of the considered lot. A comprehensive overview on the resulting sampling schemes is given in [1], *see also Prior Information in Sampling Schemes*.

In industrial implementation, Bayesian sampling schemes face two serious obstacles related to knowledge. (a) Often the specification of a prior distribution fails because of a lack of *practical* knowledge. The prior distribution should characterize the process of assorting the lots, but this process is often completely unknown to the consumer wishing to select a sampling plan for incoming inspection. (b) A further obstacle is a lack of *theoretical* knowledge. Most practitioners do not understand the concept of probability sufficiently well and, therefore, the requirement of specifying one puts them off.

Bayesian economic sampling schemes represent one extreme with respect to the available knowledge.

2 Economic Sampling Schemes

The opposite extreme is represented by the so-called minimax regret sampling schemes, which are developed and comprehensively described in [2]. The disadvantage of these plans is the often unrealistic assumption that nothing is known about the underlying production process and the actual quality level of the lot to be inspected. Ignoring any available information leads to unnecessarily high sampling cost representing that part of the overall loss which will occur with certainty.

Finally, there is a more general economic approach: The so-called Π -minimax regret approach which includes both the Bayes and the minimax approaches as special cases. In the following the Π -minimax approach is briefly outlined for the case that the lot quality indicator is given by the proportion of nonconforming items P .

The Model

We consider the quality model of sampling by attributes introduced by **Sampling Inspection of Products**, i.e., item quality indicators of the conforming/nonconforming type, and proportion nonconforming p as the lot quality indicator. The methods described can also be applied to other quality models, see [3]. The aim of sampling is to decide about acceptance or rejection of a lot to increase the economic yield. Hence, the economic consequences must be modeled meeting the following natural conditions:

1. The average loss (profit = negative loss) in case of accepting a lot with fraction nonconforming p is given by a monotonously decreasing function $C_A(p)$.
2. The average loss in case of rejecting a lot with fraction nonconforming p is given by a monotonously increasing function $C_R(p)$.
3. It is more economic to accept a faultless lot $C_A(0) < C_R(0)$, and it is more economic to reject a lot consisting of only nonconforming items $C_A(1) > C_R(1)$.
4. The loss incurred by sampling with sample size n is given by an where a denotes the sampling cost per item.

The following considerations assume a **single sampling** plan (n, c) , where n denotes the sample size and c the acceptance number. If there are not more than c nonconforming items in a sample of

size n taken from the lot, then the lot is accepted, otherwise rejected. The sample is assumed to be taken at random without replacement. Hence, the probability of accepting a lot of size N with fraction nonconforming p is given by the hypergeometric operating characteristic (see **Single Sampling by Attributes and by Variables**).

$$L_{N,n,c}(p) = \sum_{m=0}^c \frac{\binom{Np}{m} \binom{N-Np}{n-m}}{\binom{N}{n}} \quad (1)$$

On the basis of the above quantities, the initial economic conditions are given by the following characteristics:

- The indifference (break even) quality level p_0 defined by

$$C_A(p_0) = C_R(p_0) \quad (2)$$

In case of $p < p_0$ it is more economic to accept the lot. In case of $p > p_0$ it is more economic to reject the lot. In case of $p = p_0$ acceptance and rejection are economically equivalent.

- The avoidable loss is defined as the loss incurred by wrong actions performed due to not knowing the true initial condition. The avoidable loss in case $p \leq p_0$ is given by:

$$e_A(p) = \begin{cases} C_R(p_0) - C_A(p_0) & \text{if the lot is rejected} \\ 0 & \text{if the lot is accepted} \end{cases} \quad (3)$$

- The avoidable loss in case $p > p_0$ amounts to

$$e_R(p) = \begin{cases} 0 & \text{if the lot is rejected} \\ C_A(p_0) - C_R(p_0) & \text{if the lot is accepted} \end{cases} \quad (4)$$

- The expected avoidable loss for acceptable lots ($p \leq p_0$) is given by

$$E_p[e_A(p)] = [C_R(p) - C_A(p)][1 - L_{N,n,c}(p)] \quad (5)$$

- The expected avoidable loss for unacceptable lots ($p > p_0$) is given by

$$E_p[e_R(p)] = [C_A(p) - C_R(p)]L_{N,n,c}(p) \quad (6)$$

- Finally the total avoidable loss denoted $C_{N,n,c}$ is

$$C_{N,n,c}(p) = \begin{cases} E_p[e_A(p)] + an & \text{for } 0 \leq p \leq p_0 \\ E_p[e_R(p)] + an & \text{for } p_0 \leq p \leq 1 \end{cases} \quad (7)$$

The aim is to determine a sampling plan (n, c) , which minimizes in some sense the total avoidable loss.

Π -Minimax Sampling Plans

The subsequently described approach was proposed in [4] and is based on [5] and [6]. Lot proportion nonforming is considered as a random variable P resulting from a process of manufacture, storage, transport etc. It is assumed that a set Π of possible probability distributions of P is given. A sampling plan (n^*, c^*) is called a Π -minimax plan, if

$$\sup_{\pi \in \Pi} R_\pi(n^*, c^*) = \inf_{n,c} \sup_{\pi \in \Pi} R_\pi(n, c) \quad (8)$$

holds, where

$$\begin{aligned} R_\pi(n, c) &= E_\pi[C_{N,n,c}(P)] \\ &= \int_0^{p_0} E[e_A(p)] d\pi(p) \\ &\quad + \int_{p_0}^1 E[e_R(p)] d\pi(p) + an \end{aligned} \quad (9)$$

From the point of view of stochastics, Π represents the prior knowledge on lot quality, see **Prior Information in Sampling Schemes**. Three important instances may occur.

Bayes assumption (complete knowledge): If $\Pi = \{\pi_B\}$, i.e., Π contains only one element, then the probability distribution π_B represents the prior distribution and the resulting sampling plan (n_0, c_0) is a Bayes plan.

No knowledge: If Π contains all possible probability distributions of the fraction nonconforming P , then the sampling plan (n_0, c_0) is a minimax plan.

Partial knowledge: Π is a proper subset of the subset of all probability distributions. Particularly interesting

is the Γ -minimax approach where

$$\Pi = \Gamma = \left\{ \pi \mid \int_0^{p_0} d\pi(p) = \alpha \right\} \quad (10)$$

The assumption (10) means that the probability of obtaining an acceptable lot is known. This assumption is often, at least approximately fulfilled, if there is a long-term business connection between producer and consumer. Define the α -minimax cost G^* by

$$\begin{aligned} \sup_{\pi \in \Gamma} R_\pi(n, c) &= \alpha \max_{0 \leq p \leq p_0} E[e_A(p)] \\ &\quad + (1 - \alpha) \max_{p_0 \leq p \leq 1} E[e_R(p)] + an \\ &= G^*(N, p_0, \alpha; n, c) \end{aligned} \quad (11)$$

A sampling (n_0, c_0) is called a Γ -minimax plan, if it minimizes the α -minimax cost, i.e., if

$$G^*(N, p_0, \alpha; n^*, c^*) = \min_{n,c} G^*(N, p_0, \alpha; n, c) \quad (12)$$

The α -Optimal Sampling Scheme

An interesting modification of the Γ -minimax scheme is the α -optimal sampling scheme proposed in [7]. The starting position is the same as in the case of the Γ -minimax scheme. However, the α -optimal sampling scheme takes account of the fact that often the consumer has to pay for the erroneously accepted lots, whereas the producer pays for the erroneously rejected lots. Therefore, a sampling plan should be selected for which the two costs are balanced. Thus, only sample plans (n, c) are admissible for the α -optimal sampling scheme, for which

$$\alpha \max_{0 \leq p \leq p_0} E[e_A(p)] \approx (1 - \alpha) E[e_R(p)] \quad (13)$$

holds.

The side condition (13) is met by admitting only that sample size n_c for given acceptance number c , which minimizes the difference

$$\begin{aligned} D(n) &= \left| \alpha \max_{0 \leq p \leq p_0} E[e_A(p)] \right. \\ &\quad \left. - (1 - \alpha) \max_{p_0 \leq p \leq 1} E[e_R(p)] \right| \end{aligned} \quad (14)$$

4 Economic Sampling Schemes

Sampling plans (n_c, c) minimizing equation (14) are called α -balanced sampling plans. An α -balanced sampling plan (n_c^*, c^*) is called an α -optimal sampling plan if it minimizes the α -minimax cost G^* :

$$G^*(N, p_0, \alpha; n_c^*, c^*) = \min_c G^*(N, p_0, \alpha; n_c, c) \quad (15)$$

In [7] an algorithm for determining approximate α -optimal sampling plans in the case of linear loss functions C_A and C_R is given.

Conclusion

As a matter of fact most of the research articles concerning economic sampling plans were written at least 20 years ago; for a review see [8]. Nowadays, articles investigating the economic aspect of sampling are published only occasionally. Motivated by the great popularity of Taguchi's "quadratic loss to society", more recently there have been a few papers related to **acceptance sampling** as, for instance, [9] or [10]. However, assuming a quadratic loss function and instead of justifying it, just calling it a "loss to society" does not make much sense. In fact, neither a producer nor a consumer represents society and each of them should take care of their own loss and not of that of society.

Increased globalization has led to the situation in which many companies operate production locations distributed all over the world with ever-increasing concentration in the so-called low-cost countries. This trend has increased significantly the importance of outgoing and incoming inspection. A considerable part of the overall costs is represented by inspection and related costs in many industries.

A reduction in these costs would considerably increase their competitiveness. Therefore, what is needed are user-friendly economic sampling schemes, which could and should replace the inefficient and costly AQL sampling plans still used in industries worldwide.

Prior Information in Sampling Schemes

Introduction

The choice of a sampling scheme and the amount of inspection is guided, at least informally, by prior information on quality. Formal rules for adapting the rigor of inspection to past inspection records are, for example, the switching rules contained in many standard sampling schemes like MIL-STD-105E or ISO 2859, *see* **Attributes Sampling Schemes in International Standards** and **Variables Sampling Schemes in International Standards**. These are often based on heuristic arguments, but there are also rules derived from a strict mathematical treatment. An interesting recent example is an article by Bailie and Klaassen [1]. However, these authors do not model prior information explicitly either. Here we are concerned with the formal models of prior information. Together with a loss function, in a very broad sense, these may be used to design optimal sampling strategies or to analyze and compare the performance of existing sampling schemes.

In the “Bayesian approach”, prior knowledge is modeled in terms of a prior distribution. According to Hald [2], a complete statistical model of sampling inspection should contain the expected distribution of submitted lots according to quality (prior distribution) and the cost of sampling inspection, acceptance, and rejection. The best sampling plan is defined as the one within the class minimizing the average costs. This is essentially the paradigm of Bayesian decision theory, *see* [3]. However, the latter is not restricted to costs in a monetary sense. It only requires a numerical goal function that measures the consequences of possible decisions. Bayesian sampling plans will be introduced in the first section of this chapter. In practice, basic assumptions are often not satisfied. Therefore, modifications may be necessary and these will be addressed in the second section.

Bayesian Sampling Plans

A useful guide to practitioners on how and when to use Bayesian sampling plans has been described by Calvin [4]. The basic concepts are introduced in

the following example. We use the framework established by chapters **Sampling Inspection of Products** and **Single Sampling by Attributes and by Variables**: A lot of items $1, \dots, N$ is described by the sequence $z_1, \dots, z_N$ of item quality indicators. Lot quality q is a function of the item quality indicators. Let $z_{i1}, \dots, z_{in}$ be the item quality indicators in a sample of size n from the lot. A sample-based decision rule is represented by a function $\Delta(z_{i1}, \dots, z_{in}) = d$. A **single sampling** plan is given by (n, Δ) where the values d of Δ range over $d = a$ “accept” and $d = r$ “reject”. There are essentially two types of cost models: “type A” means that the costs of items in the sample do not depend on the decision about the remainder of the lot, whereas in “type B” the costs of defective items in the sample and those in the remainder of the lot depend in the same way on the final decision.

Introductory Example

In single sampling by attributes, the item quality indicators are binary variables where $z_i = 1$ means that the i -th item is defective (nonconforming) and $z_i = 0$ means that it is nondefective (conforming). The lot quality indicator is the number $m = z_1 + \dots + z_N$ of defective items in the lot, or the fraction defective $p = mN^{-1}$.

Linear Cost Model of Type B. As a simple example, we introduce a linear cost model of type B. For the interpretation of the parameters, *see* [2]. The cost of decision d per item with characteristic z is given by $k_d(z) = a_d + b_d z$, i.e., it is a_d if the item is conforming and $a_d + b_d$ if the item is nonconforming. The cost K_d of acceptance and rejection of the whole lot is the sum of the individual costs, it depends obviously on p :

$$\begin{aligned} K_d &= \sum_{i=1}^N k_d(z_i) = Na_d + mb_d = N(a_d + b_d p) \\ &= N k_d(p) = K_d(p) \end{aligned} \quad (1)$$

Moreover, there are sampling costs $n \cdot s$, where s is the sampling cost per item.

Prior Distribution and Bayesian Decision Rule.

The decision d is based on the number X of defective items in a random sample without replacement.

2 Prior Information in Sampling Schemes

For fixed m , its probability distribution $P[X = x|m]$ is hypergeometric. In addition, there is a prior distribution $\Psi(m)$ for m (prior to sampling), i.e., the number of nonconforming items in the lot is a random variable M with distribution Ψ . In a frequency interpretation, m varies from lot to lot according to Ψ .

Given a particular observation $X = x$, Bayes theorem allows us to calculate the posterior probability of $M = m$ as $P[M = m|X = x] = P[X = x|m]\Psi(m) \left(\sum_{l=0}^N P[X = x|l]\Psi(l) \right)^{-1}$. From this, the expected posterior loss of decision d can be derived as

$$E(K_d|X = x) = \sum_{m=0}^N K_d \left(\frac{m}{N} \right) P[M = m|X = x] \quad (2)$$

One should accept if $E(K_a|X = x) \leq E(K_r|X = x)$ and reject otherwise. It can be shown that there exists c such that $E(K_a|X = x) \leq E(K_r|X = x)$ if $x \leq c$, where $c = -1$ is admitted with the interpretation “rejection regardless of the outcome of the sampling”. This justifies using a sampling plan (n, c) . This is the first way of looking at Bayes: we have several possible decisions; given an observation, a decision is chosen, which has the smallest posterior loss. However, this does not answer the question which **sample size** n should be used. For this purpose, one has to compare the expected costs for different sampling plans, including sampling costs. For fixed m , the average loss of (n, c) is given by

$$R\left(n, c \middle| \frac{m}{N}\right) = n \cdot s + k_a \left(\frac{m}{N} \right) P[X \leq c|m] + k_r \left(\frac{m}{N} \right) P[X > c|m] \quad (3)$$

Considered as a function of p , $R(n, c|p)$ is called the risk function of (n, c) . Its expected value with respect to Ψ ,

$$R_\Psi(n, c) = E_\Psi \left[R\left(n, c \middle| \frac{m}{N}\right) \right] = \sum_{m=0}^N \Psi(m) R\left(n, c \middle| \frac{m}{N}\right) \quad (4)$$

is called the Bayes risk of using (n, c) . A Bayesian sampling plan (n_Ψ, c_Ψ) minimizes $R_\Psi(n, c)$. This constitutes the second way of looking at Bayes: a decision rule tells us which action to take depending

on the observation. We choose the “Bayesian rule” which minimizes the expected costs.

Priors Related to the Production Process, Additional Examples

Frequently, the distribution of the quality of the lot is related to the distribution of quality in the production process: if the items of lots of size N are drawn independently at random from a production process with constant probability π of producing a defective item, the number m of defective items in the lot varies according to the binomial frequency function $b(m|N, \pi)$. If π itself varies at random from lot to lot according to a distribution $W(\pi)$, the distribution of lot quality becomes a mixed binomial distribution

$$\Psi(m) = \int_0^1 b(m|N, \pi) dW(\pi) \quad (5)$$

This model is frequently mentioned in the literature: it allows analysis of various situations where sampling inspection is advantageous, and derivation of adequate strategies, see [2]. For example, W may represent a production process in statistical control with occasional out-of-control periods. The lots produced during these periods are considered as outliers, and if the product in the in-control state is satisfactory, the problem of sampling inspection is to detect the outliers. Formally, W can be taken as a beta distribution with outliers.

Cost Model of Type A under Single Sampling. In such environments, cost models of type A have a simple structure. Thyregod [5] provides a very elegant treatment, which is restricted to neither the attributes sampling nor the linear cost models. The item quality indicators $Z_1 \dots Z_N$ are assumed to be independent and distributed according to a density $f(z|\omega)$, where ω is the process parameter. This includes various models, in particular: (a) attributes sampling where $Z \in \{0, 1\}$, $\omega = P[Z = 1]$ and (b) sampling by variables where Z is normally distributed with expectation μ and standard deviation σ and $\omega = (\mu, \sigma)$. The parameter ω varies in the production process from lot to lot according to a distribution $W(\omega)$. The decision $d \in \{a, r\}$ is based on a sample of size n , which can be identified with $Z_1 \dots Z_n$. The cost of the decision depends only on the remaining $N -$

n item characteristics, it is the sum of the individual costs $k_d(z_j)$ of the items $j = n + 1, \dots, N$. The function $k_d(z)$ is not restricted to a special type; it includes the above cost model, slight generalizations (e.g., sampling by variables with upper specification limit $U : k_d(z) = a_d$, if $z \leq U$ (item good) and $= a_d + b_d$, if $z > U$ (item defective)) as well as nonlinear cost functions. The cost of sampling is the sum of individual sampling costs $k_s(z_i)$ of the items in the sample.

For $i = a, r, s$, let $k_i^*(\omega) = \int k_i(z) f(z|\omega) dz$ be the expectations of the costs with respect to $f(z|\omega)$. Moreover, let $k_s^* = \int k_s^*(\omega) dW(\omega)$ be the overall expected sampling costs. Since, for given ω , the n observations in the sample are independent from the remaining $N - n$ variables, the expected cost when using the sampling plan (n, Δ) is $R_W(n, \Delta) = n \cdot k_s^* + (N - n) r_W(n, \Delta)$, where

$$r_W(n, \Delta) = \int [P[\Delta = a|\omega] k_a^*(\omega) + P[\Delta = r|\omega] k_r^*(\omega)] dW(\omega) \quad (6)$$

Equation (6) has the formal structure of equations (3) and (4), with Ψ replaced by W and $R(n, c|p)$ replaced by the integrand in brackets in equation (3). This means that the original decision problem regarding the lot is formally equivalent to a decision problem regarding the process parameter ω with prior distribution W . A Bayesian sampling plan minimizes $R_W(n, \Delta)$. Thyregod [5] shows that it has usually a familiar structure: there is a test statistic t , and the lot is accepted if $t \leq c$. For example, in the case of a normally distributed quality characteristic with parameters μ and σ and upper specification limit U ,

$$t = \sqrt{n}(\bar{X} - U) S^{-1} \quad (7)$$

where S is the sample standard deviation.

Extensions and More Recent Results

The Bayesian approach is neither restricted to decision rules of this simple structure nor to monetary costs. For example, Bayesian multistage or **sequential sampling** plans may be designed to minimize the average sample size, which now plays the role of a risk function. Here the class of decision rules is much richer than above. A considerable amount of literature exists on Bayesian sampling,

and with increasing computer **power** more sophisticated models can be studied. For example, Gonzalez *et al.* [6] consider the number of defects per unit of product, whereas Chen *et al.* [7] introduce a Bayesian variable **acceptance sampling** scheme for life testing with mixed censoring. In both the articles, different types of nonlinear loss functions are used.

Modifications of Full Bayes

Robustness with Respect to Prior and Economic Model

Correct assignment of the prior distribution and a monetary cost model, as well as the stability of the prior are problematic issues of the Bayesian approach. General concepts of **Bayesian robustness** are discussed by Berger [3]. Bayesian sampling plans often have a poor discriminating power, which is a problem if the assumed prior distribution is misspecified or unstable. Therefore, Hald [2] recommends using restricted Bayesian sampling plans, where the Bayes risk is minimized within a smaller class of sampling plans with sufficient discriminating power. If full information about costs is not available, a partial cost function or the expected amount of inspection can be minimized under conventional constraints on the consumer's or the producer's risk, see [2]. The latter approach avoids the problem of estimating cost parameters completely. Bayes theorem also allows us to calculate posterior risks. In this spirit, Schafer [8] suggests to minimize the sample size under constraints on the posterior risk to the producer and the consumer risk.

Γ -Minimax

A concept which automatically yields more robust strategies is partial prior information, also called Γ -minimax. For example, Krumbholz and Pflaumer [9] derive sampling strategies which minimize expected costs subject to prior information on the probability that the fraction nonconforming does not exceed a certain upper bound. In a similar spirit, Collani [10] considers the so-called α -optimal sampling schemes, see **Economic Sampling Schemes**. These conditions are examples of "generalized moment conditions" of the prior. Other generalized or ordinary

moments can be estimated more easily from past inspections (see below), but the calculation of a corresponding sampling strategy is usually a complex “ Γ -minimax” problem. This can be solved in a numerically efficient way by semi-infinite programming, see [11].

Availability of Information on the Prior

If the fraction nonconforming p or the process parameter ω varies from lot to lot according to a prior Q , it is possible to gain information about Q from past inspections. However, one does not observe p or ω directly. The observable distribution is the mixture of the conditional distribution of the test statistic, given p or ω , with mixing distribution Q . Methods which use information about the observable distribution to derive a Bayesian decision rule are called **empirical Bayes**; for a general outline we refer again to [3], in particular, the section titled “Nonparametric Empirical Bayes Analysis”. Empirical Bayes has been applied to sampling inspection several times. Another way is to estimate ordinary or generalized moments of the prior indirectly from the observable distribution [12], and to use a Γ -minimax sampling plan. This method is able to incorporate information about the uncertainty of the estimator, for example, a confidence band around the empirical estimate of the marginal distribution.

Adaptive Sampling Strategies

A final issue is stability of the prior. Rendtel and Lenz [13] have developed a sampling system based on sequential tests, which is able to adapt to changing priors. Here it is not necessary to model these changes explicitly. There have also been attempts to model prior information by stochastic processes more general than independent and identically distributed (i.i.d.), but it seems that these have not gained much popularity.

Reliability Sampling

Introduction

Reliability sampling is a part of **acceptance sampling** (see **Sampling Inspection of Products**) that is dedicated to the control of those quality characteristics of a product, which are related to its lifetime. In contrast with classical acceptance sampling, in reliability sampling procedures, such as lifetime tests, the quality of sampled items is evaluated using tests that last in time. A further distinction between classical acceptance sampling and reliability sampling stems from the fact that the latter is rather used for the control of process parameters than for the control of finite lots or batches of products. Therefore, popular methods of sampling by attributes are seldom used in reliability sampling. On the other hand, methods of sampling by variables, whose applicability for the acceptance sampling of finite lots is questionable, are very useful in the context of reliability sampling.

Statistical procedures of reliability sampling can be roughly divided into two general groups according to the quality model considered (see **Sampling Inspection of Products** for quality models in acceptance sampling). (a) Sampling procedures used for the control of a fraction (probability) nonconforming $\theta = p$ (probability of failing before prespecified time, probability of incorrectly performing a certain mission, probability of not passing a special test, etc.). The underlying item quality indicators X_i are binary variables where $X_i = 0$ indicates conformance and $X_i = 1$ indicates nonconformance. This case is considered in the section titled “Reliability Sampling by Attributes”. (b) Sampling procedures used for the control of reliability parameters related to time (mean time to failure (MTTF), mean time between failures (MTBF), constant hazard, or failure rate, etc.). The underlying item quality indicators X_i are real-valued variables expressing time to failure, time between failures, and so on. This case is considered in the section titled “Reliability Sampling for **Lifetime Distributions**”.

In reliability sampling, it is common practice to define two characteristic values of the quality parameter θ : an acceptable value θ_0 (often called *producer’s quality*) and an unacceptable value θ_1 . Reliability sampling plans are methods for testing the null hypothesis $H_0 : \theta \leq \theta_0$ against the alternative

$H_1 : \theta \geq \theta_1$. Let α be the probability of wrong rejection of H_0 (producer’s risk), β the probability of wrong acceptance of H_1 (consumer’s risk), and $L(\theta)$ the probability of accepting the null hypothesis as a function of the true value θ of the considered parameter. Then, the reliability sampling plan is designed in such a way that the two requirements $L(\theta_0) \geq 1 - \alpha$ and $L(\theta_1) \leq \beta$ are fulfilled. This design is well known in classical acceptance sampling (see **Single Sampling by Attributes and by Variables**). However, the difference between classical and reliability acceptance sampling plans lies in the way the statistical data are collected. We discuss these differences in detail in the next section.

Reliability Sampling by Attributes

The item quality model of acceptance sampling by attributes distinguishes conforming and nonconforming items (see **Single Sampling by Attributes and by Variables**). In the context of reliability, conformance is usually understood as the correct functioning during a certain period, correct performing of a certain action, or positively passing a special trial (e.g., an environmental trial). If conformance and nonconformance are clearly defined, all well-known sampling plans by attributes, like those described in the international standard ISO 2859-1 [1], may be applied. Specific attributes plans for reliability sampling can be found in the international standard IEC 61123 [2]. The basic reliability sampling plans presented in [2] are the curtailed sequential sampling plans by attributes (see **Multiple Sampling Plans** for information on sequential sampling). In contrast with the original sequential sampling procedures, a sample-size curtailment is introduced in the plans given in [2]. If the cumulative number of tested items reaches the curtailment value n_t and yet no decision on acceptance or rejection has been achieved, inspection terminates and the decision is then taken by comparing the observed number of nonconforming items, e.g., the number of failures, with specific curtailment values of the acceptance number. Parameters of the plans given in [2] are calculated using simple approximate formulas proposed by Wald [3] for non-curtailed sampling plans. Thus, the exact statistical characteristics of the curtailed sequential sampling plans given in this standard are different from the designed ones. Curtailed sequential sampling plans

by attributes based on exactly computed statistical properties can be found in the latest version of the international standard ISO 8422 [4]. In addition to curtailed sequential sampling plans, IEC 61123 [2] gives also reliability sampling plans where the number of trials (**sample size**) or the number of observed failures are predetermined. In all reliability sampling plans mentioned in this section, the design principles are those described in the previous section, i.e., they are based on two prespecified points on the operating characteristic (OC) function of the sampling plan.

Reliability Sampling for Lifetime Distributions

General Description

When reliability requirements are related to lifetimes (survival times) of items, reliability sampling procedures are different from those of classical sampling by variables. In classical sampling by variables the values of the quality characteristic of interest are observed for all items in the sample. In reliability tests, due to unavoidable limitations imposed on the possible time of the reliability test, not all lifetimes of tested items are observed. This feature of lifetime tests is known as *censoring*. Censoring arises in various ways. In the case of type II censoring, the test is terminated after the occurrence of the r th failure. Thus, the number of observed failures is fixed, but the length of the lifetime test is random. In such a case, the lifetimes of the remaining $n - r$ tested items are known only to exceed the time of the r th failure. In the case of type I censoring, the test is terminated after a predetermined time t_B . For this type of censoring the test time is fixed, but the number of observed failures is random. There exist also more complex censoring schemes like progressive censoring (see the section titled “Reliability Sampling Plans for Complex Censoring Schemes”).

The presence of censoring makes the design of reliability sampling plans very complicated. Only for exponentially distributed lifetimes, sampling plans are relatively easily designed. Moreover, the efforts of many researchers resulted in some practical procedures for the cases of the Weibull and the lognormal distributions of lifetimes. For other probability distributions of lifetimes, reliability sampling procedures are practically nonexistent.

Reliability Sampling for the Exponential Distribution

The exponential distribution, defined by the density function

$$f(t) = \frac{1}{\mu} \exp\left(-\frac{t}{\mu}\right) = \lambda \exp(-\lambda t), \quad t > 0 \quad (1)$$

is the most popular statistical model that has been used for the analysis of lifetimes. The reason for its popularity stems from the fact that it is completely defined by only one parameter: the expected value μ , or its reciprocal – the constant hazard rate $\lambda = 1/\mu$. This allows reliability analysts to estimate basic reliability characteristics when only few reliability data are available.

In the statistical analysis of lifetime data described by the exponential distribution, we use the fact that all information from a sample is subsumed by two statistics: the observed number of failures r , and the **total time on test** (total observed lifetimes) T . From a practical point of view this feature is very important: the same information comes from lengthy lifetime tests of few items and shorter tests of many items.

The most popular reliability sampling procedure is a sequential one, originally proposed by Epstein and Sobel [5]. Its curtailed version is described in the international standard IEC 61124 [6]. For this test the observed number of failures r is plotted against the cumulative (total) time on test. If the cumulative time on test T , for the observed number of failures r , is greater than or equal to an acceptance critical value T_a , the test is terminated, and the specified reliability requirement is regarded as being complied with. If, on the other hand, this time is smaller than or equal to a rejection critical value T_r , the test is terminated, and the specified reliability requirement is regarded as not being complied with. If time T , for the observed number of failures r , lies between these two critical values, no decision can be taken, and the test is continued. When the number of observed failures exceeds the curtailment value, the test is terminated, and the specified reliability requirement is regarded as not being complied with. The international standard [6] also provides fixed time/failure terminated reliability sampling plans. For these sampling plans decisions rules of accepting or rejecting compliance are made when the test time for termination has been reached, or the acceptable number of failures has been exceeded. The general guidance on

how to use these reliability sampling plans is given in the standard MIL-STD-781D [7]. The sampling plans of this American military standard are given in the handbook *MIL-HDBK-781A* [8]. The sampling plans given in [6] and [8] are practically the same.

Reliability Sampling for the Weibull and Other Lifetime Distributions

The Weibull distribution is described by the following density function

$$\frac{\beta}{a} \left(\frac{t}{a}\right)^{\beta-1} \exp \left[-\left(\frac{t}{a}\right)^{\beta} \right] t > 0$$

where $\beta > 0$ is the shape parameter, and $a > 0$ is the scale parameter of the distribution. When the value of β is known, we can transform the Weibull distribution to the exponential distribution using a simple transformation $Z = T^{\beta}$. In such a case, we can use simple reliability sampling plans designed for the exponential distribution. However, when the value of the shape parameter is not known, the design of reliability sampling plans is not so simple. Sequential sampling plans, which are the most popular reliability sampling plans, have not been proposed yet for the Weibull case. However, several authors proposed reliability sampling plans with type II censoring by the number of observed failures for the transformed lifetime variable $X = \ln T$, which is distributed according to the extreme value probability distribution. First plans of this type were proposed by Fertig and Mann [9] who used best linear unbiased estimators (BLUEs) for the **estimation** of the parameters of the distribution. The sample statistic is the standardized logarithm of the p th quantile of the Weibull distribution. The sampling plan is given by the sample size n , the censoring number of failures r , and the critical value k of the test statistic. Calculations are based on an approximation of the probability distribution of the sample statistic. Another reliability sampling plan was proposed by Schneider [10], who used the maximum-likelihood estimators (MLEs) of the parameters of the distribution. The decision criterion is typical for sampling plans by variables. The result of the reliability test is positive (acceptance) if $\hat{\mu} - k\hat{\sigma} \geq \ln L$, where $\hat{\mu}$ and $\hat{\sigma}$ are the estimators of the parameters $\mu = \ln a$ and $\sigma = 1/\beta$, respectively, k is the acceptability constant, and L is the lower specification limit for the lifetime. The parameters of

the sampling plan are computed from the corrected asymptotic distribution of the MLEs. Similar sampling plans have also been proposed for the lognormal and the gamma probability distributions.

Reliability Sampling Plans for Complex Censoring Schemes

In real reliability sampling experiments, certain items are removed from the test at its different stages, for instance, to investigate physical **degradation** processes that lead to future failures. When a prespecified number of tested items are withdrawn from the test at the **moments** of failures of some other items, the censoring scheme is known as *progressive censoring of type II*. The general methodology for the design of such reliability sampling plans was proposed by Balasooriya and coauthors. The case of the exponential distribution is considered in [11], and the case of the Weibull distribution is described in [12]. The results presented in these papers, and in other recently published papers on similar topics, are rather far from being applicable in practice.

Reliability Sampling Plans Based on the Results of Accelerated Life Tests

Reliability acceptance sampling plans for highly reliable components may be impractical due to the very long testing times required. In accelerated life tests (ALTs), introduced in the 1960s, items are tested at two or more stress levels that are higher than the normal one. In ALT failures are expected to occur earlier than in normal life tests, and thus the test time may be significantly reduced. There exist two general approaches in ALT. In overstress (or constant-stress) life tests a sample is divided in two or more subsamples tested at different stress levels. In step-stress life tests the whole sample is tested at one (usually lower) stress level for a certain time, and then the test is continued at the next (usually higher) stress level. The number of stress levels in test of both types may be greater than two, but reliability sampling plans based on ALT are usually designed for two levels of stress. Moreover, it is assumed that the functional form of the relationship between the expected lifetime and the stress level is known. The first acceptance sampling plans based on ALT were proposed in the 1990s, and since then many different procedures have been proposed in literature, mainly

for the exponential and the Weibull distributions. For example, constant-stress acceptance sampling plans were proposed by Yum and Kim [13], for the exponential distribution, and by Bai *et al.* [14], for the Weibull and lognormal distributions. For the exponential distribution, step-stress sampling plans were proposed by Bai *et al.* [15]. Chung *et al.* [16] have proposed such plans for the Weibull distribution.

Bayes Reliability Sampling Plans

The reliability sampling plans described in the previous sections of this article are based on purely statistical requirements. All relevant information comes from tested samples. Two extensions are possible: (a) inclusion of economic parameters, e.g., sampling costs, losses induced by wrong decisions, and so on; and (b) inclusion of certain prior information about the reliability of items, especially useful in case of highly reliable objects. Statistical procedures that use information of types (a) and (b) are named *Bayesian procedures*. In the area of reliability sampling an interesting general framework for the design of optimal Bayesian sampling plans in the case of exponential distribution was proposed by Dunsmore and Wright [17]. Bayesian **life test** plans for the Weibull distribution with given shape parameter are also given by Zhang and Meeker [18]. In both instances, however, ready-to-use tables of sampling plans do not exist, and therefore particular sampling plans are to be determined by a user using general algorithms given in the aforementioned papers.

Variables Sampling under Measurement Error

Introduction

Variables sampling (*see Single Sampling by Attributes and by Variables*) assumes that the measurement error in measuring the characteristic under investigation is negligible, i.e., the standard deviation of measurement is no more than 10% of the process (or within-lot) standard deviation of the quality characteristic. However, especially in materials testing and in chemical analysis this assumption very often does not hold. In such cases the random variable Y describing the measurement result obtained at a sampled item can be modeled as the sum

$$Y = X + X_{\text{meas}} \quad (1)$$

where $X \sim N(\mu; \sigma^2)$ is the random variable describing the variation of the quality characteristic between items and $X_{\text{meas}} \sim N(0; \sigma_r^2)$ is the random variable, independent of X , describing measurement variation; its expectation is zero since it is assumed that the measurement process is unbiased. In the special case of no measurement error, we have $X_{\text{meas}} \equiv 0$ and hence, $Y = X$, i.e., the measured value y obtained at an item is equal to its “true” value x .

In what follows, only the *type B procedure* of **Single Sampling by Attributes and by Variables** is considered with the *one-sided* case where an upper limit (UL) is specified.^a The fraction of nonconforming items above UL in the process behind the lot is

$$\pi = P(X > UL) = 1 - \Phi\left(\frac{UL - \mu}{\sigma}\right) \quad (2)$$

where μ is the process mean, σ is the process standard deviation, and $\Phi(\cdot)$ is the cumulative distribution function of the standardized **normal distribution**. A **single sampling** plan for inspection by variables is a statistical test of the null hypothesis $H_0 : \pi \leq AQL := \pi_1$ against the alternative hypothesis $H_1 : \pi > \pi_1$ where AQL is specified acceptable quality level.

In [1] and [2] the effect of measurement error on the operating characteristic (OC) function of a single sampling plan for inspection by variables is investigated under the assumption that the ratio of

the measurement standard deviation to the process standard deviation is known. Wilrich [3] deals with the case where each sampled item is measured more than once and an upper bound for the ratio of the measurement standard deviation to the process standard deviation is available.

μ Unknown, σ^2 and σ_r^2 Known

If each of n_σ^* sampled items is measured m times as is often the case in materials testing and in chemical analysis ($m = 1$ is the special case of no repeated measurements), and if

$$\bar{\bar{Y}} = \frac{1}{n_\sigma^* m} \sum_{i=1}^{n_\sigma^*} \sum_{j=1}^m Y_{ij} \quad (3)$$

is the mean of the measurements X_{ij} ; $i = 1, \dots, n_\sigma^*$; $j = 1, \dots, m$ then an estimator of the fraction of nonconforming items, π , is

$$\hat{\Pi} = 1 - \Phi\left(\frac{UL - \bar{\bar{Y}}}{\sigma}\right) \quad (4)$$

If π_c is the critical value of the test, the lot will be accepted for

$$\hat{\Pi} \leq \pi_c \quad (5)$$

or equivalently

$$\frac{UL - \bar{\bar{Y}}}{\sigma} \geq u_{1-\pi_c} := c_\sigma^* \quad (6)$$

$$Z_\sigma := \bar{\bar{Y}} + c_\sigma^* \sigma \leq UL \quad (7)$$

where $u_{1-\pi_c}$ is the $(1 - \pi_c)$ -quantile of the standardized normal distribution.

For given parameters (n_σ^*, c_σ^*) of the single sampling plan the OC function is

$$\begin{aligned} L(\pi) &= P(Z_\sigma \leq UL) \\ &= \Phi\left(\sqrt{\frac{n_\sigma^*}{1 + \gamma_r^2/m}}(u_{1-\pi} - c_\sigma^*)\right) \end{aligned} \quad (8)$$

where

$$\gamma_r = \sigma_r / \sigma \quad (9)$$

is the ratio of the measurement standard deviation to the process standard deviation. A comparison

2 Variables Sampling under Measurement Error

with the case without measurement error (see **Single Sampling by Attributes and by Variables**, Table 3) shows that the OC is equal to the one without measurement error if $c_\sigma^* = c_\sigma$ and

$$n_\sigma^* = n_\sigma(1 + \gamma_r^2/m) \quad (10)$$

measurement error, if it exists, needs the **sample size** to be increased by the factor $(1 + \gamma_r^2/m)$ to keep the OC function of the plan unchanged. If the measurement standard deviation is not larger than 10% of the process standard deviation, i.e., $\gamma_r^2 \leq 0.01$, the influence of measurement error is negligible. As a larger m is chosen, as more vanishes the uncertainty caused by measurement error, and the sample size does not need to be increased very much.

The single sampling plan with the smallest sample size n_σ^* for which

$$L(\pi_1) \geq 1 - \alpha, \quad L(\pi_2) \leq \beta \quad (11)$$

where $P_1(\pi_1; 1 - \alpha)$ and $P_2(\pi_2; \beta)$ with $0 < \pi_1 < \pi_2 < 1$ and $0 < \beta < 1 - \alpha < 1$ are two given points on the **OC curve** which are given by

$$n_\sigma^* = \left(\frac{u_{1-\alpha} + u_{1-\beta}}{u_{1-\pi_1} - u_{1-\pi_2}} \right)^2 \left(1 + \frac{\gamma_r^2}{m} \right) \quad (12)$$

$$c_\sigma^* = \frac{u_{1-\beta}u_{1-\pi_1} + u_{1-\alpha}u_{1-\pi_2}}{u_{1-\alpha} + u_{1-\beta}} \quad (13)$$

u_p is the p -quantile of the standardized normal distribution; n_σ^* has to be rounded off to the next largest integer.

μ, σ^2 and σ_r^2 Unknown

In this section the process standard deviation σ and the measurement standard deviation σ_r are assumed to be unknown. The cases of one measurement per item and of $m > 1$ measurements per item are treated separately.

One Measurement per Item

If each of n_s^* sampled items is measured once ($m = 1$) then the test statistic is

$$Z_s := \bar{Y} + k_s^* S \quad (14)$$

where

$$\bar{Y} = \frac{1}{n_s^*} \sum_{i=1}^{n_s^*} Y_i, \quad S^2 = \frac{1}{n_s^* - 1} \sum_{i=1}^{n_s^*} (Y_i - \bar{Y})^2 \quad (15)$$

are sample mean and sample variance of the sample of size n_s^* , respectively.

For given parameters (n_s^*, c_s^*) of the single sampling plan, the OC function is

$$\begin{aligned} L(\pi) &= P(Z_s \leq UL) = P(T_{n_s^*-1, \delta} \geq c_s^* \sqrt{n_s^*}) \\ &= 1 - F(c_s^* \sqrt{n_s^*}) \end{aligned} \quad (16)$$

where

$$\delta = \sqrt{\frac{n_s^*}{1 + \gamma_r^2}} u_{1-\pi} \quad (17)$$

and $T_{n_s^*-1, \delta}$ is noncentral t-distributed with $\nu = n_s^* - 1$ **degrees of freedom** and noncentrality parameter δ . Unfortunately, the OC function depends on the ratio γ_r of the measurement standard deviation to the process standard deviation, a value which is hardly known, because the production process and the measurement process are completely different processes for which the relationship of the standard deviations would only be known if the standard deviations themselves are known.

If (n_σ, c_σ) are the parameters of the sampling plan for the case of no measurement error and known standard deviation which has the desired properties $L(\pi_1) \geq 1 - \alpha$ and $L(\pi_2) \leq \beta$ the matching plan for the case of unknown standard deviation and no measurement error ($\gamma_r = 0$) has the parameters $c_s = c_\sigma$ and

$$n_s = n_\sigma(1 + c_\sigma^2/2) \quad (18)$$

If the single sampling plan is designed for the case of no measurement error and a measurement error exists when it is applied, the probabilities of acceptance for all fractions π of nonconforming items in the process with $0 < \pi < 1$ will be smaller than without measurement error so that the requirement $L(\pi_1) \geq 1 - \alpha$ is not anymore fulfilled; see Figure 1. On the other hand, if the single sampling plan is designed for the case of measurement error, expressed as a given ratio γ_r , and measurement error is smaller during its application, i.e., the actual γ_r is smaller than the value used for the design, the requirement $L(\pi_2) \leq \beta$ is not fulfilled.

Figure 1 The OC curves of the single sampling plan ($n_s^* = 25$, $c_s^* = 1.83$), $m = 1$ measurement per item, which fulfills the requirements $L(1\%) \geq 1 - \alpha = 93\%$ and $L(8\%) \leq \beta = 10\%$ if $\gamma_r = 0$, but fails if it is used in the case of measurement error, $\gamma_r = 0.5$ and $\gamma_r = 1$. Each symbol represents the acceptance frequency on the basis of 1000 simulation runs

m Measurements per Item

In any case, an existing measurement error, if its standard deviation σ_r is unknown, changes the OC function and, hence, the risks of the single sampling plan, in an uncontrolled manner. However, this difficulty can be partly overcome if each sampled item is measured m times ($m = 2, 3, \dots$) and a one-way analysis of variance is performed, i.e., the total **sum of squares** is broken down into one between sampled items and one within them:

$$\underbrace{\sum_{i=1}^{n_s^*} \sum_{j=1}^m (Y_{ij} - \bar{\bar{Y}})^2}_{Q_{\text{total}}} = m \underbrace{\sum_{i=1}^{n_s^*} (\bar{Y}_i - \bar{\bar{Y}})^2}_{Q_{\text{between}}} + \underbrace{\sum_{i=1}^{n_s^*} \sum_{j=1}^m (Y_{ij} - \bar{Y}_i)^2}_{Q_{\text{within}}} \quad (19)$$

where

$$\bar{Y}_i = \frac{1}{m} \sum_{j=1}^m Y_{ij}; i = 1, \dots, n_s^* \quad (20)$$

and

$$\bar{\bar{Y}} = \frac{1}{n_s^* m} \sum_{i=1}^{n_s^*} \sum_{j=1}^m Y_{ij} \quad (21)$$

is the mean of the measurements $Y_{ij}; i = 1, \dots, n_s^*; j = 1, \dots, m$.

As test statistic for the test we use

$$Z_s := \bar{\bar{Y}} + c_s^* S_w \quad (22)$$

where

$$S_w^2 = \max(0, (S_{II}^2 - S_I^2)/m) \quad (23)$$

and

$$S_I^2 = \frac{Q_{\text{within}}}{n_s^* (m - 1)}, \quad S_{II}^2 = \frac{Q_{\text{between}}}{n_s^* - 1}. \quad (24)$$

The OC function of the single sampling plan (n_s^* , c_s^*) under parameters (γ_r , m) obtained by using a normal approximation of Z_s is

$$L(\pi) = P(Z_s \leq UL) = \Phi\left(\frac{\sqrt{n_s^*}}{A}(u_{1-\pi} - c_s^*)\right) \quad (25)$$

with

$$A = A(c_s^*, \gamma_r, m) = \sqrt{1 + \frac{\gamma_r^2}{m} + \frac{(c_s^*)^2}{2m^2} \left[(m + \gamma_r^2)^2 + \frac{\gamma_r^4}{m - 1} \right]} \quad (26)$$

If (n_σ, c_σ) are the parameters of the sampling plan for the case of no measurement error and known standard deviation which has the desired properties $L(\pi_1) \geq 1 - \alpha$ and $L(\pi_2) \leq \beta$ the matching plan for the case of measurement error, expressed by γ_r , has the parameters $c_s^* = c_\sigma$ and

$$n_s^* = A^2 n_\sigma \quad (27)$$

Unfortunately, as for $m = 1$ the OC function and, hence, n_s^* depend on γ_r . However, since $c_s^* = c_\sigma$ is determined only by $P_1(\pi_1; 1 - \alpha)$ and $P_2(\pi_2; \beta)$ for all values of γ_r , the OC functions of all these sampling plans have the common point $(\pi, L(\pi))$ with π given by $u_{1-\pi} = c_\sigma$ and $L(\pi) = \Phi(0) = 0.5$. Increasing γ_r turns the OC around this 50% point (point of indifferent quality) so that it becomes more flat and does not anymore fulfill both the requirements $L(\pi_1) \geq 1 - \alpha$ and $L(\pi_2) \leq \beta$. On the other hand, if the sampling plan has been designed for a given γ_r and is applied in a situation with a smaller γ_r , the OC becomes steeper.

In most of the practical applications an upper bound for the ratio γ_r is available, e.g., the measurement standard deviation is not larger than the process standard deviation ($\gamma_r \leq 1$), and the single sampling plan can be designed for measurement error with

Figure 2 The OC curves of the single sampling plan ($n_s^* = 52$, $c_s^* = 1.83$), $m = 2$ measurements per item, which fulfills the requirements $L(1\%) \geq 1 - \alpha = 93\%$ and $L(8\%) \leq \beta = 10\%$ if $\gamma_r = 1$ and performs better for $\gamma_r = 0.5$ and $\gamma_r = 0$. Each symbol represents the acceptance frequency on the basis of 1000 simulation runs

respect to this upper bound; see Figure 2. This would have the advantage that for all situations for which the measurement error is smaller than this upper bound the actual risks α of the producer and β of the consumer would both be smaller than the values used for the design of the plan. Smaller measurement error would pay for both sides!

Example

A single sampling plan for inspection by variables shall be determined so that for $\pi = 1\%$ the probability of acceptance is $L(\pi_1) \geq 1 - \alpha = 93\%$, and for $\pi_2 = 8\%$ it is $L(\pi_2) \leq \beta = 10\%$.

For the case of σ known, no measurement error ($\gamma_r = 0$) and $m = 1$ we find $c_\sigma = c_s^* = 1.83$ and $n_\sigma = n_s^* = 9$ from equations (13) and (12). For unknown σ we get $c_s = c_s^* = c_\sigma = 1.83$ and $n_s = n_s^* = 25$ from equation (18). Figure 1 shows the design criteria for the plan and the OC curve according to equations (8) and (16) which coincide. If σ is unknown and this sampling plan (where each sampled item is measured once) is used in the presence of measurement error, the OC function depends on $\gamma_r = \sigma_r/\sigma$. Figure 2 shows the OC curves of the plan ($n_s^* = 25$, $c_s^* = 1.83$) for $\gamma_r = 0; 0.5$ and 1.0 . To

check the accuracy of the approximations, results of the simulations are added.

If a measurement error exists and the variances σ^2 and σ_r^2 are known, the sample sizes for $\gamma_r = 1$ are, according to equation (12), $n_\sigma^* = 18, 14, 12, 12, 11$ for $m = 1, 2, 3, 4, 5$ respectively. From $m = 9$ to $m = 212$ the sample size is $n_\sigma^* = 10$ and for $m \geq 213$ it is $n_\sigma^* = 9$, i.e., equal to the sample size for the case of no measurement error.

If a measurement error exists and the variances are unknown the sample sizes for $\gamma_r = 1$ and $m = 2, 3, 4$ are, according to equations (26) and (27), $n_s^* = 52, 40, 35$, respectively. Figure 2 shows the OC curves of the plan ($n_s^* = 52$, $c_s^* = 1.83$) for $m = 2$ if the actual measurement error is $\gamma_r = 1$ (the design value), 0.5 and 0 (i.e., smaller than the design value). Both the producer risk α and the consumer risk β are smaller than the required values. Again, to check the accuracy of the approximations, results of the simulations are added.

Endnotes

^aIn the case of a specified lower limit (LL) the fraction of nonconforming items is $\pi = P(X < LL) = \Phi\left(\frac{LL - \mu}{\sigma}\right)$. In equations (7), (14) and (22) the negative sign has to be used and the lot is accepted if the test statistic is greater than or equal to LL .

Attributes Sampling under Classification Error

Introduction

The effect of inspection error in **acceptance sampling** has been studied extensively. For example, see Bennett *et al.* [1], Dorris and Foot [2], Ghosh [3], Hong *et al.* [4], Johnson *et al.* [5–7], Maghsoodloo [8], and Moskowitz and Fink [9]. The effect of inspection error on group testing has also been considered at length by Graff and Roeloffs [10], Huang *et al.* [11], and Johnson *et al.* [12–14]. The monograph by Johnson *et al.* [15] provides a detailed consolidation of the work in this field in a way that this brief article cannot do. Instead, this article serves as an introduction.

Single Sampling

We consider a lot of size N which has D nonconforming items. We will select a single random sample of n units for inspection. Each unit in the sample will be classified as either conforming (C) or nonconforming (NC). We let p_1 be defined as the probability that an NC item is correctly identified as NC and p_2 be the probability that a C item is incorrectly identified as NC. We let the random variable, Y be the number of NC items in the sample and Z be the number of items identified as NC from the sample. The probability that there are $Y = y$ NC items in the sample has a hypergeometric distribution. That is

$$\Pr[Y = y] = \frac{\binom{n}{y} \binom{N-n}{D-y}}{\binom{N}{D}} = \frac{\binom{D}{y} \binom{N-D}{n-y}}{\binom{N}{n}}, \quad \max(0, n - N + D) \leq y \leq \min(n, D) \quad (1)$$

When $p_1 < 1$, only some of the NC items in the sample will be identified as NC. The conditional probability for $Z = z | Y = y$ is binomial,

$$P[Z = z | y] = \binom{y}{z} p_1^z (1 - p_1)^{y-z} \quad (2)$$

Therefore, the probability that $Z = z$ items are identified as NC is

$$\Pr[Z = z] = \frac{\sum_{y \leq z} \binom{D}{y} \binom{N-D}{n-y} \binom{y}{z} p_1^z (1 - p_1)^{y-z}}{\binom{N}{n}} \quad (3)$$

$$E[Z] = np_1 \frac{D}{N} \quad (4)$$

and

$$\text{Var}[Z] = n \frac{(N-n)D}{N-1} \left(1 - \frac{D}{N}\right) + p_1(1 - p_1) \frac{nD}{N} \quad (5)$$

When $p_2 > 0$, some of the C items in the sample will also be identified as NC. The conditional probability that $z - w$ of these $n - y$ C items will be identified as NC is

$$\binom{n-y}{z-w} p_2^{z-w} (1 - p_2)^{n-y-z+w} \quad (6)$$

Therefore, when $p_2 > 0$ and $p_1 < 1$,

$$\begin{aligned} \Pr[Z = z] &= \frac{\sum_{w \leq z} \binom{D}{y} \binom{N-D}{n-y} \binom{y}{w} p_1^w (1 - p_1)^{y-w}}{\binom{N}{n}} \\ &\times \binom{n-y}{z-w} p_2^{z-w} (1 - p_2)^{n-y-z+w} \end{aligned} \quad (7)$$

$$\begin{aligned} E[Z] &= np_1 \left(\frac{D}{N}\right) + np_2 \frac{(N-D)}{N} \\ &= n[p \cdot p_1 + (1 - p)p_2] = n\bar{p} \end{aligned} \quad (8)$$

and

$$\text{Var}[Z] = n\bar{p}(1 - \bar{p}) - n(n-1) \frac{(\bar{p}^2 - \bar{p}^2)}{(N-1)} \quad (9)$$

where $p = D/N$, $\bar{p} = p_1 \cdot p + p_2(1 - p)$ and $\bar{p}^2 = \{Dp_1^2 + (N-D)p_2^2\}/N$. $\bar{p}$ is the probability that a randomly selected item is classified as NC.

When $p_1 = 1$ and $p_2 = 0$, there is no inspection error and $\Pr[Z = z]$ is equal to $\Pr[Y = z]$. When $p < 1$ and/or $p_2 > 0$ the operating characteristic function, $\Pr[Z \leq c] = \sum_{z=0}^c \Pr[Z = z]$ can be substantially different from the values obtained using equation (1), i.e. the values that would be obtained

2 Attributes Sampling under Classification Error

Table 1 $P[Z = 0]$ for acceptance sampling with $N = 100$, $D = 5$, and $n = 5$

	$p_2 = 0$	$p_2 = 0.025$	$p_2 = 0.05$	$p_2 = 0.075$	$p_2 = 0.1$
$p_1 = 0.75$	0.8236	0.7269	0.6395	0.5608	0.4900
$p_1 = 0.8$	0.8126	0.7170	0.6306	0.5527	0.4827
$p_1 = 0.85$	0.8017	0.7071	0.6217	0.5447	0.4755
$p_1 = 0.9$	0.7909	0.6974	0.6129	0.5368	0.4684
$p_1 = 0.95$	0.7802	0.6877	0.6041	0.5289	0.4614
$p_1 = 1$	0.7696	0.6781	0.5955	0.5212	0.4544

without inspection error. For example, the probability of accepting a lot under zero-defect inspection is shown in Table 1 for various values of p_1 and p_2 . The probability decreases if $p_2 > 0$, i.e. if C items may be incorrectly classified as NC. The probability of accepting the lot decreases if $p_1 < 1$, i.e. if some NC items may be classified as C. In Table 1, the effect of $p_2 > 0$ is seen to be more substantial. Similarly, the values for $E[Z]$ and $\text{Var}[Z]$ can differ substantially from those given by $E[Y]$ and $\text{Var}[Y]$. In acceptance sampling, the effect of inspection error should be considered when selecting the sampling plan (n, c) , as described by Ferrell and Chhoker [16].

Multiple Sampling

Instead of taking a single sample of size n , we may take k samples without replacement. The samples may be of different sizes $n = (n_1, n_2, \dots, n_k)$, resulting in random number of NC items $Y = (Y_1, Y_2, \dots, Y_k)$ in each sample as well as random number of items $Z = (Z_1, Z_2, \dots, Z_k)$ that are identified (correctly or incorrectly) as NC in each sample. When there is no inspection error, $Z = Y$. If $k = 2$, this procedure is called *double sampling*. In double sampling, we take a random sample of size n_1 . If Z_1 , the number of NC items (either correctly or incorrectly identified) is less than or equal to a threshold a_1 , accept the lot. If $Z_1 \geq a'_1$, reject the lot. If $a_1 < Z_1 < a'_1$, we take another sample of size n_2 . If $Z_1 + Z_2 \leq a_2$ we accept the lot. Otherwise the lot is rejected. In multiple sampling, additional samples can be selected before deciding whether to accept or reject a lot. For more information on multiple sampling see **Multiple Sampling Plans**.

The probability $p_1 = (p_{1,1}, p_{1,2}, \dots, p_{1,k})$, of correctly identifying NC items as NC and $p_2 = (p_{2,1}, p_{2,2}, \dots, p_{2,k})$ of incorrectly identifying C items as NC may either be the same in each sample (the equal error probabilities case) or the error probabilities may

be different in each sample. Either way, the joint distribution of Y is a multivariate hypergeometric

$$\begin{aligned} \Pr[Y = y] &= \frac{\binom{D}{y} \binom{N-D}{n-y}}{\binom{N}{n}} \\ &= \frac{\prod_{i=1}^k \binom{n_i}{y_i} \binom{n - \sum y_i}{D - \sum y_i}}{\binom{N}{D}} \end{aligned} \quad (10)$$

And, following the development for **single sampling**,

$$\begin{aligned} \Pr[Z = z] &= \frac{\sum_{w \leq z} \binom{D}{y} \binom{N-D}{n-y}}{\binom{N}{n}} \\ &\times \prod_{j=1}^k \binom{y_j}{w_j} p_{1,j}^{w_j} (1 - p_{1,j})^{y_j - w_j} \\ &\times \binom{n_j - y_j}{z_j - w_j} p_{2,j}^{z_j - w_j} \\ &\times (1 - p_{2,j})^{n_j - y_j - z_j + w_j} \end{aligned} \quad (11)$$

Acceptance probabilities can be calculated using this expression. These probabilities are tabulated in [7].

Group Testing (Screening)

Dorfman [17] was concerned with testing large numbers of blood samples for syphilis. To save time and money, he mixed together blood from a group of n_0 samples and tested the entire mixture instead of the individual samples. If the test was negative, testing was completed with only one test. If the test result

was positive, each sample would be tested resulting in a total of $n_0 + 1$ tests. When the inspection procedure is perfect, the savings are maximized by letting n_0 equal $(\text{proportion NC})^{-1}$.

When there are inspection errors, it is possible that the group is incorrectly classified as NC. This can lead to unneeded individual testing. If individual samples are tested, they also may be incorrectly classified. In addition, it is possible that a group contains NC items but it is classified as C. As before, for the individual testing, p_1 is defined as the probability that an NC item is correctly identified as NC and p_2 is the probability that a C item is incorrectly identified as NC. In addition, p_0 is defined as the probability that the group is correctly declared NC when at least one sample in the group is NC and p'_0 is the probability that the group is incorrectly identified as NC when all items in the group are C. The probability that an NC item will be correctly classified is $p_0 p_1 < p_1$. The probability that a C item is correctly classified as $P_0^*(n_0)(1 - p'_0 p_2) + \{1 - P_0^*(n_0)\}(1 - p_0 p_2)$ where $P_0^*(n_0) = (N - D - 1)^{n_0-1} / (N - 1)^{n_0-1}$ is the probability that the group has no NC items given that a particular item is C.

Since the probability of a correct classification of an NC item is decreased by the screening process, the value of screening must come from increased probability of correctly identifying C items and/or a reduction in the number of tests needed. The expected number of tests is $1 + n_0\{p_0 - (p_0 - p'_0)P_0(n_0)\}$ where $P_0(n_0) = (N - D)^{n_0} / N^{n_0}$ is the probability that a group has no NC items.

Acceptance Sampling with Rectification

In acceptance sampling, lots that are not accepted can be either discarded or rectified. Rectification, i.e. replacing or discarding all NC units after 100% inspection of rejected lots is frequently used when manufacturing costs are high. See **Rectification Sampling Schemes** for general information on rectification sampling. Greenberg and Stokes [18] used the information obtained in rectification to estimate the number or rate of NC units, i.e. the average outgoing quality (AOQ) in a series of outgoing lots after zero-defect sampling. The estimator for the number of NC units is

$$\hat{U}_{GS} = \sum_{Y_{i1} > 0} Y_i \frac{1 - P_i}{P_i} \quad (12)$$

Where Y_i is the number of items identified as NC in lot i and P_i is the probability that at least one NC unit will be chosen from lot i in the initial random sample.

$$P_i = \begin{cases} 1 - \frac{\binom{N - Y_i}{n}}{\binom{N}{n}} & \text{if } Y_i \leq N - n \\ 1 & \text{otherwise} \end{cases} \quad (13)$$

Anderson, Greenberg and Stokes [19] show that inspection errors can have a serious biasing effect on this estimator. An alternative estimator allows for c defect sampling and reduces both the **bias** and **mean squared error**.

$$\begin{aligned} \hat{U}_{ca} &= \sum_{I_{ca,i}=1} \frac{Y_i}{p_1 - p_2} \left(\frac{1}{P_{ca,i}} \right) - \sum_{i=1}^T \frac{N p_2}{p_1 - p_2} \\ &\quad - \sum_{i=1}^T \frac{Y_{i1} - n p_2}{p_1 - p_2} p \\ &\quad - \sum_{I_{ca,i}=1} \frac{Y_{i2} - (N - n) p_2}{p_1 - p_2} p_1 \\ &= \frac{1}{p_1 - p_2} \left\{ \sum_{i=1}^T \left[\frac{Y_i I_{ca,i}}{P_{ca,i}} - p_1 (Y_{i1} + Y_{i2} I_{ca,i}) \right] \right. \\ &\quad \left. - T p_2 (N - n p_1) + N_{ca} p_2 p_1 (N - n) \right\} \quad (14) \end{aligned}$$

where $N_{ca} = \sum_{i=1}^T I_{ca,i}$ is the total number of lots rectified from a set of T lots. $I_{ca,i}$ is 1 if lot i is rectified under a modified (n, c) sampling plan or zero otherwise. A small proportion, α , of lots with c or fewer errors in the sample are rectified in addition to all lots with more than c errors. The modification is required to ensure that $P_{c,i}$ is always greater than zero. AOQ is thus estimated to be $\hat{U}_{ca} / NT$. The average total inspections (ATI) will increase slightly because of this modification. ATI increases when $p_2 > 0$, i.e. when C items may be incorrectly classified as NC and decreases when $p_1 < 1$, i.e. when some NC items may be classified as C. These effects may balance out, but more often the effect of $p_2 > 0$ is larger since there are (hopefully) more C than NC items.

Estimating Error Probabilities

Generally it is assumed that the misclassification probabilities p_1 and p_2 are known. In practice this is rarely the case, so the interesting quantities are often tabulated to see how sensitive they are to classification error. If $p = D/N$ is the proportion of devices that are C, and as usual p_1 is the probability that an NC item is correctly identified, and p_2 is the probability that a C item is incorrectly identified as NC, then Z , the number of items identified as NC allows us to estimate the parameter $p \cdot p_1 + (1 - p)p_2$ and does not help us to estimate p , p_1 , or p_2 . If items are tested only once, we will never know whether errors occur in the testing process. It is only when we see items that are identified by one test as C and as NC by another test that we realize that $p_1 < 1$ and/or $p_2 > 0$, i.e., there are classification errors. To estimate these parameters some items must be tested more than once.

The problem of estimating p_1 and p_2 has also been studied extensively (see [20] and [12]) and is acknowledged to be among the most challenging in **attribute sampling**. When neither p_1 nor p_2 can be considered negligible, it is necessary to inspect some items at least three times to estimate p , p_1 , and p_2 . Here, we consider the case in which a number of items, say N , are inspected exactly three times. The simplest estimators of p_1 , p_2 , and p assume that items that fail at least twice are NC and the items that fail fewer times are C. Then p_1 , p_2 , and p are estimated using the number of correct outcomes from the tests. That is

$$\hat{p}_{1,EZ} = \frac{2N_2 + 3N_3}{3(N_2 + N_1)} \quad (15)$$

$$\hat{p}_{2,EZ} = \frac{N_1}{3(N_0 + N_1)} \quad (16)$$

and

$$\hat{p}_{EZ} = \frac{N_2 + N_3}{N} \quad (17)$$

where N_j is the number of items declared nonconforming j times, $j = 0, 1, 2, 3$. If $\hat{p}_{1,EZ}$ is undefined because $N_2 + N_3 = 0$, then we set $\hat{p}_{1,EZ} = 1$. Similarly, if $\hat{p}_{2,EZ}$ is undefined, we set its value equal to zero. Alternatively, maximum likelihood estimators (MLEs) of p_1 and p_2 can be obtained. The MLEs for $\hat{p}_{1,ML}$ and $\hat{p}_{2,ML}$ maximize $L = \prod_{j=0}^3 [P(j)]^{N_j}$,

where

$$P(j) = p \binom{3}{j} p_1^j (1 - p_1)^{3-j} + (1 - p) \binom{3}{j} p_2^j (1 - p_2)^{3-j} \quad (18)$$

Note that it is necessary to simultaneously maximize L with respect to p_1 , p_2 , and p .

Surprisingly, in [19] Anderson, Greenberg, and Stokes found that $\hat{p}_{1,EZ}$ and $\hat{p}_{2,EZ}$ often performed better than $\hat{p}_{1,ML}$ and $\hat{p}_{2,ML}$ and always performed at least as well for values that are typical of this application.

BETSY S. GREENBERG

Database Systems for Acceptance Sampling

Introduction: Database Systems

A database system is a triple of a database **DB**, a set of application programs **AP** and a database management system **DBMS**. A database **DB** over a database schema S consists of a finite set R of relations (tables) $r \subseteq \text{dom}(A)$ and a set of integrity constraints, Σ , where $\text{dom}(A)$ is the value set defined by the cross-product of the ranges of all attributes $A \in A$. The attributes have specific data types like *int*, *real*, *string*, *Boolean*, and so on. The application programs support planning and management of batch inspection. The integrity constraints assure technical, statistical, and semantic coherency of the data stored in any $r \in R$ at any time [1].

Database Systems for Acceptance Sampling

With respect to the granularity of data in **DB** and the objective of data retrieval we differentiate between on-line transaction processing (OLTP) and on-line analytical processing (OLAP) databases. OLTP databases used for “on-line transaction processing” have been in use since 1970 and are specially tuned to manage operative mass data from the shop floor [2]. They are used for on-line control like **acceptance sampling**, monitoring or **process control**, and in off-line control, for instance, for storing data of designed experiments. A typical query of **quality control** (QC) administration is “What is the inspection state (‘in control’, ‘accepted’, or ‘rejected’) of a batch submitted by company C ‘last week’ with part-id = 4711?”

Contrarily, OLAP databases (“analytical transaction processing”) are designed to support the middle QC manager or the chief executives of a company with respect to planning, decisions and controlling. They were introduced in business from 1990 on [3]. They store business indicators as aggregated and grouped data by using statistical functions like *avg* (average), *sum*, *min*, *max*, and *counts* (frequency), combined with the grouping operator *group-by*. A typical indicator might be “Percentage of rejected

items in incoming batches grouped by supplier-id, part-id, and quarter”.

A major advantage of a database system is to hide details of the storage, the control of concurrent access and the maintenance of the data from the users. On the *physical level*, the database designer describes in a physical schema $S_p \subseteq S$ how the database is technically organized, stored and accessed. For example, in a distributed database system, data with lowest granularity is recorded on the shop floor. Daily grouping and summarizing of such measurements generates low-level aggregated data which is entered into a departmental data warehouse. Aggregation over departments produces an enterprise-wide view. Further details are skipped here, cf. [4]. The external schema $S_u \subseteq S$ provides a view for each authorized user u according to his individual (“personalized”) profile. Views are important for enforcing data security and usage comfort. Access – as read or write – to the database is enabled by the (declarative) structured query language called *SQL* which is a *de facto* standard [4]. A conceptual schema $S_c \subseteq S$ is an abstract model of the real world focusing on the frame of discernment. It consists of (R, Σ) defining relations (tables) and related constraints. The DBMS furthermore supplies a data definition language to generate the tables and to provide a mapping from the conceptual level to the physical implementation.

We present now, an example of a conceptual schema of a QC database system for an adaptive acceptance sampling system which combines a skip-lot system and the Mil-Std. 105D [5]. This OLTP database system combines two principles of adaptability used in industry: lot-by-lot inspection with varying sample sizes or skipping lots according to the history of quality. We note that attributes which play the role of an identifier of objects (primary key) are underlined. The most elementary tables are those for suppliers, parts, and quality characteristics (attributes) which are an intrinsic part of any enterprise information system like SAP, Oracle Business Suite, and so on.

```
Supplier (supplier_id, name, info),  
Part (part_id, name, description),  
Attribute (attribute_id, name, description).
```

Furthermore a “supply list” is needed as a subset $L \subseteq \text{Supplier} \times \text{Part}$:

```
SupplyPart (supplier_id, part_id,  
conditions).
```

2 Database Systems for Acceptance Sampling

The QC department is responsible for the design of the basis sampling plans of **attribute sampling** for reduced, normal and tightened inspection indexed by batch size, class and average quality level (AQL):

Basis Sampling Plans (lower_batch_size, upper_batch_size, AQL_level, (sample_sizes, acceptance_numbers)).

The same is true for switching rules which are an inherent part of adaptive systems. In the MISL (mixed MIL-Std 105D and Skip-Lot sampling system) system the states 0 to 2 correspond to the states in Mil-Std 105D, i.e., tightened, normal, and reduced inspection levels, while the inspection states 3 to 5 are skip-lot states with varying skip sizes or batch inspection frequencies:

Switching_Rules (AQL_level, relaxation_number, skip_size3, skip_size4, skip_size5).

As the AQL is assumed to be invariant with respect to suppliers, we have to know the AQL value for each quality characteristic and each part :

Part_Attribute (part_id, attribute_id, AQL_level).

Note that the test department, the test device, as well as the measurement method used in the inspection phase can easily be added as further attributes to that relation.

Any system, especially a dynamic one, needs information about the state of inspection of incoming batches. Assuming that incoming batches are strictly sequenced, we get:

Inspection-state (supplier_id, part_id, attribute_id, batch_id, date, inspection_level, inspection_no, skip_no).

As the decision to inspect a batch or not and the **sample size** of batch inspection depends on the so-called history of quality of an attribute, i.e., on the sequence of former inspection states, we need to store the history of inspection for each attribute of every batch supplied by every supplier:

History(date, batch_id, attribute_id, supplier_id, part_id, update_indicator, sample_size, acceptance_no, no_of_defects, batch_size).

We summarize by representing the corresponding entity-relationship (ER) model in Figure 1.

We illustrate the ease of querying of OLTP databases by checking whether or not batch b_1 of

Figure 1 ER model for (adaptive) acceptance sampling

electronic switches supplied on October 27, 2007, passed inspection with respect to the tolerance of electric resistance (TER):

```

select no_of_defects ≤ acceptance_no
from History
where date = 2007-10-27 and batch_id
= 'b 1' and attribute_id = 'TER'.
    
```

Data Warehousing for Acceptance Sampling

While querying of an operative database is user-friendly and is efficiently performed owing to tree-indexed structures and hashing [6], retrieval of aggregated data with range queries becomes more troublesome. Such deficiencies caused the development of OLAP databases called *data warehouses*. The main data structure is the data cube which is called *multiway table* in statistics [3]. It can be defined as a tuple (statistical function f , [summary attribute A], set of dimensions D). The symbol $[]$ means that this term is optional. Facts are composed of a statistical function and – optionally – a summary attribute like “number of defects” or “diameter”. Dimensions are attributes which are not pairwise (strong or weak) functionally dependent [7] cf. Figure 2. For example, the data cube *Supplier-Report* ($100 * \text{acceptance rate}, \emptyset, \{\text{part_id}, \text{supplier_id}, \text{month/quarter/year}\}$) represents the percentage of accepted incoming batches grouped by part, supplier, and time. Note that attributes like part or time may have domains which are partially ordered,

Figure 2 Data cube with one fact table and three-dimensional tables

i.e., form hierarchies. The cube operators needed are cube projection (dicing), cube selection (slicing) and hierarchy traversal (roll-up, drill-down). A cube, which can again be viewed as a table, can be materialized (permanently stored and updated) or virtual, i.e., computed “on the fly”. The database administrator has to find the best trade-off between retrieval time and storage size.

Evidently, the mapping from OLTP to OLAP databases is not simple [1]. OLTP–OLAP data transformations and retrieval of data combine elements from the set of cube operators O , the set of aggregation functions F , and the set of transformations T . Admissible operations should guarantee their statistical and semantic coherency. For instance, consider the transformation T of a consumption rate measured in l/100km to miles/gallon, which is a nonlinear transformation. Testing cars with respect to consumption or mileage is usually done within and outside a city, and the measured rates of consumption or mileage are averaged. Of course, as a linear operator (average) and a nonlinear transformation T are not generally commutative, contradicting decision may be caused when either the consumption rate or the mileage rate is used [8].

Outlook

SAP Netweaver, IBM’s database management system DB2, Microsoft’s SQL server and Oracle’s Business Suite offer a broad spectrum of automated **data collection** facilities and retrieval functionality for mass data. Although the border between querying and statistical data analysis is becoming vaguely more and more, there still remains a demand in industry for explorative data analysis, which can be handled by added-on **data mining** or “intelligent” data analysis tools [9, 10], for the underlying methodology.

HANS-J. LENZ

Acceptance Sampling in Modern Industrial Environments

Introduction

In the mass production environments of the first half of the twentieth century, **quality control** rested on the triple *sorting* principle of *inspecting* product, *detecting* inappropriate product, and *sorting out* inappropriate product. Accordingly, statistical **product inspection** (SPI) based on sampling was the first strong branch of modern statistical quality control (SQC). Two prominent SPI schemes are the Dodge–Romig tables developed at Bell Telephone Laboratories in the 1920s and 1930s, and the Military Standard (MIL-STD) series developed in the 1940s and 1950s for the U.S. armament industry. The sorting principle is clearly expressed by the definition of the purpose of sampling inspection given by H. F. Dodge and H. G. Romig (see [1, p. 11]): “The purpose of the inspection is to determine the acceptability of individual lots submitted for inspection, i.e., sorting good lots from bad.”

Industry changed drastically in the second half of the twentieth century. Quality control adopted a new principle: *provision* for appropriate product, instead of sorting out inappropriate product. Consequently, emphasis shifted from product inspection to issues like design control, **process control** maintenance, and service. The same change of paradigms occurred in SQC. However, SPI can play a reasonable role in modern industrial quality control, if its status, purpose, and methods are defined adequately. Some essential challenges for modern, useful, and promising SPI are discussed in the subsequent sections.

The Adjunct Role of SPI in Modern Product Control

SPI is a tool of product quality control, where the term *product* is used in a broad sense to include any completed identifiable entity like materials, parts, products, services, or data. Product control is located at the interface of two parties: a *supplier* or *vendor* or *producer* as the party providing product and a *customer* or *consumer* as the party receiving product.

Traditional product control relied on the sorting principle at the interface of supplier and consumer. Modern product control primarily relies on quality provision and prevention at the interface. The particular task of the interface is to integrate supplier and consumer into joint and concerted efforts to create and maintain favorable conditions for quality in design, manufacture, handling, transport, and service. In this scheme, inspection may be useful, however not as the primary tool of product control, but in an adjunct role, subordinate to the guiding principles of provision and prevention.

The adjunct role of SPI is expressed in [2] in marked contrast to the sorting view of Dodge and Romig [1]: “The shipper must understand the acceptance sampling plan in order to be sure that the quality control of the production process provides lots of a quality sufficient to meet his objective. This is the basic principle of acceptance sampling – to assure the production of lots of acceptable quality. The primary purpose is not to discriminate between acceptable and nonacceptable lots.” The subordinate role of SPI is connected with the following purposes:

1. **Information and quality measurement purpose:**
SPI serves as an economical supplementary source of information on the product quality level. In particular, SPI is used to learn about the product quality level if the supplier–consumer interface is new and sufficient quality records do not exist.
2. **Incentive purpose:**
Continuous SPI puts an incentive on the supplier’s quality efforts.
3. **Protection purpose:**
SPI protects against sudden and unexpected shifts in the quality level.
4. **Precaution purpose:**
SPI serves as a precaution for the consumer, if the supplier–consumer interface is new or if the quality efforts of the supplier are not completely reliable.

Adaptiveness and Prior Knowledge on Product Quality

The interest in inspection varies along the history of the supplier–consumer interface. Continuing satisfactory quality records enhance mutual confidence

and reduce the interest in precautionary inspection. Confronted with deteriorating quality, the supplier will feel the need for tighter inspection. Accordingly, the design and the implementation of SPI should provide an adaptive learning mechanism, which methodically varies the amount of inspection (**sample size**) along with changes in the supplier–consumer relations. In particular, the adaptation mechanism should be able to react on continuing satisfactory quality records by not only changing the sample size but also by redefining the purpose of inspection, e.g., by switching to the no-sampling alternative.

Most customary acceptance **sampling schemes** are mechanisms to vary the sample size as a function of product quality records: the switching rules in the MIL-STD series (*see* **Attributes Sampling Schemes in International Standards**); sample size varying with the process proportion nonconforming in the Dodge–Romig rectification scheme (*see* [1] and **Rectification Sampling Schemes**); sample size varying according to some prior information on the distribution function of product quality (*see* **Economic Sampling Schemes; Prior Information in Sampling Schemes**). However, all these approaches give no guidelines on when to switch to the no-sampling alternative. Feigenbaum [3] and Deming [4] give all-or-none rules to choose between rectifying 100% inspection and acceptance without inspection on grounds of a linear cost model with the process proportion nonconforming as an input parameter; see the presentation of Deming’s $k_1 - k_2$ inspection policy in **Skip Lot and Chain Sampling**. An additional rule vaguely recommends sampling inspection only if the process proportion nonconforming is “close” to some breakeven point p_0 . Joyce Orsini’s scheme, as presented by Deming [4], specifies the meaning of “close to breakeven point” by an exact interval I around p_0 , and recommends sampling inspection with sample size $n = 200$, if the process proportion nonconforming is in I . Such rules are simple to administer, but their basis is heuristic.

Obviously, a suitable mechanism of representing and exploiting prior knowledge and forecasts on product quality is a necessary condition for adaptiveness of an SPI scheme. The absence of prior knowledge parameters is one of the weaknesses of the popular MIL-STD scheme. Most other inspection schemes are based on some more or less refined assumption on prior knowledge on product quality. The analysis of Feigenbaum [3] and Deming [4]

stipulates at least some interval of variation of the process proportion nonconforming to be known. The Dodge–Romig rectification scheme (*see* [1] and **Rectification Sampling Schemes**) is based on a similar assumption. Bayes schemes, as discussed by **Prior Information in Sampling Schemes**, assume the complete distribution function of product quality to be known – an assumption, however, which is hardly ever met in industrial practice. A reasonable alternative is to assume some incomplete knowledge of the distribution function of product quality. A simple and practicable instance of this approach is the α -optimal sampling scheme (*see* **Economic Sampling Schemes**).

Among industrial SPI standards, only ISO 13448 provides a systematic adaptive mechanism that depends on information on product quality and covers the entire range between no sampling and 100% inspection. ISO 18414 at least allows for successive reduction of sample size in response to a good quality history (*see* **Sampling in Industrial Standards** for more detailed descriptions). Both standards are recent, issued in 2004, 2005, and 2006, and broad industrial experience is still missing.

The importance of collecting and using information on product quality has been propagated by quality assurance literature and the ISO 9000 standard. Modern industrial environments are characterized by highly automated and intensively monitored processes of manufacture, handling, and shipping. Product quality data are often exchanged at the supplier–consumer interface. Both in theory and in practice of SPI, a satisfactory and generally accepted framework for exploiting such prior information is still missing. The issues of adaptiveness and prior information continue to be imminent challenges for SPI.

The Economic Concern of SPI

Product control is a business activity. As such, it is subject to an economic cost–benefit analysis: costs incurred by control activities have to be compared with the economic benefit obtained from maintaining a specified product quality level. The following economic parameters are relevant for product **inspection policies**: cost of inspection, profit or loss incurred from accepting or rejecting product of a specified quality level. See [3] for a detailed economic analysis.

The economic concern of SPI is ideally reflected by an *economic SPI scheme* with an economic model, an economic objective function, and an economic design built on optimizing the objective function (see **Economic Sampling Schemes** for details). Sometimes rigorous economic designs may be impractical because the parameters of the economic model are not fully known. In such cases, other designs may be used (see **Sampling Inspection of Products** for a survey). In any case, however, the values of the central design parameters, in particular the values of critical quality limits, should be chosen on grounds of economic reasoning.

The analysis and due consideration of quality economics, in particular the economic cost–benefit analysis of quality control activities, has been propagated by quality management literature (see [3] or [4]) and by industrial standards like the ISO 9000-9004 series (see [5]). However, this propaganda had little impact on the practice of SPI. The MIL-STD series and its national and international derivatives continue to be the most widely used SPI schemes in industry. These standards contain neither an economic model nor economic guidelines on how to choose their central design parameter, the acceptable quality level (AQL). As stated by Deming [4], p. 430, it is no astonishment to learn that MIL-STD “can lead to a plan whose total cost is double the cost of 100 per cent inspection”. The situation is not better for the Dodge–Romig scheme: the choice of central design parameters like LTPD (lot tolerance percent defective) and AOQL (average outgoing quality limit) is not supported by economic guidelines. None of the national or international SPI standards has adopted a precise economic framework. Economic SPI schemes, even of simple type as the scheme considered by **Economic Sampling Schemes** or of convenience type as Joyce Orsini’s rules, have not been accepted by industrial practice.

The current practice of SPI does not reflect the economic concern of SPI. It is to be feared that many applications rather involve redundant costs than contribute to the economical control of product quality.

Definition of Quality Levels

The purpose of product control is to assure an acceptable product quality level. An adequate and precise

definition of quality levels refers to a quantitative product quality indicator γ (see **Sampling Inspection of Products**). Quality levels are distinguished by means of threshold values of γ . In case of a simple binary quality model, an acceptable quality level is distinguished from an unacceptable (rejectable) quality level by means of a *breakeven quality* or *breakeven point*. **Sampling Inspection of Products** and **Economic Sampling Schemes** discuss the derivation of the breakeven quality from an economic model.

A precise distinction between acceptable and rejectable product quality by a breakeven point is postulated by **quality management** literature, e.g., [3] or [4]. Among SPI schemes, only economic schemes support the definition of a break even quality. Customary SPI schemes like MIL-STD or Dodge–Romig scheme use a variety of parameters seemingly related to quality levels, like AQL, LTPD, CQ (consumer’s quality), PQ (producer’s quality), LQL (limiting quality level), and RQL (rejectable quality level) (see **Sampling Inspection of Products**). The usefulness of these parameters is restricted: (a) they are not defined uniquely and precisely and most definitions are purely operational; (b) the role as quality thresholds is never made explicit; and (c) there are no guidelines on how to assign values to the parameters.

Most problematic is the AQL in MIL-STD. MIL-STD-105E [6] vaguely defines as follows: “When a continuous series of lots is considered, the AQL is the quality level which, for the purposes of sampling inspection, is the limit of a satisfactory process average.” Diverging interpretations of this definition have been given. Some authors consider the AQL directly as a breakeven quality. Others, like the authors of [7] or [3], establish functional relationships between Breakeven qualities calculated on the grounds of economic models and the AQL in MIL-STD. Although the cost models are the same, the relations to the AQL differ drastically. The disastrous consequence is that totally different sampling plans result from the same economic constellation. Confronted with such confusion, industrial practice has widely refrained from determining specific AQL values in specific business situations. As a pragmatic solution, AQL values are negotiated by contractual parties, or dictated by large companies, or recommended as standards in specific industrial segments. The sampling plans chosen under such precepts make no reasonable contribution to product

control. On the contrary, they incur additional costs, and lead to barely comprehensible and potentially dangerous conclusions.

SPI under Modern Quality Requirements

Modern industrial environments prescribe tight quality requirements and achieve outstanding quality levels. The Six Sigma scheme aspires to a proportion nonconforming level below 3.4 parts per million (ppm). [8] reports on plants and companies achieving extremely small nonconforming rates between 0 and 2 ppm over long periods. In contrast, customary SPI schemes consider the smallest proportion nonconforming thresholds of 0.01% AQL in MIL-STD-105E or 0.5% LTPD in the Dodge–Romig scheme. MIL-STD-105E [6] overtly admits that it is useless under strict quality requirements: “The sampling plans described in this standard are applicable to AQL’s of 0.01 percent or higher and are therefore not suitable for applications where quality levels in the defective parts per million range can be realized.” Strangely enough, MIL-STD sampling plans with AQLs up to 4% are used in industrial segments that in other respects are striving for extremely tight quality levels, like the electronic or nuclear industry. Such applications are merely pro forma, without any real impact on product quality. Their only effect is to cause additional costs. Among industrial SPI standards, only ISO 14560 accounts for relatively small proportion nonconforming thresholds, with the smallest so-called LQL at 500 ppm (*see Sampling in Industrial Standards* for more information). Broad industrial experience with this recent standard issued in 2004 is still missing.

The formation of sound inspection schemes for high-quality product at economically tolerable sample sizes is an imminent challenge for SQC. This task is closely related to two other aspects discussed in this article: (a) accounting for previous information on product quality is essential for reducing sample size; (b) the problem of measuring the product quality level is particularly serious in case of extreme values of product quality indicators.

Quality Measurement as a Purpose of SPI

Montgomery [9, p. 646], states: “It is the purpose of acceptance sampling to sentence lots, not to estimate the lot quality. Most acceptance sampling plans

are not designed for **estimation** purposes.” This is a correct description of the present state of acceptance sampling. However, requirements for modern acceptance sampling as discussed above suggest that the purpose of acquiring information by measuring an unknown quality parameter, e.g., a proportion nonconforming, should play a much more important role than it presently does. This purpose requires sufficiently reliable and sufficiently accurate measurement procedures, taking into account any available prior knowledge on product quality. According to the specific situation and interest, the measurement targets may be lot or process parameters.

Measurement of Lot Quality Parameters

Consider the measurement of an unknown proportion nonconforming in a lot by sampling. In most customary approaches (*see Prior Information in Sampling Schemes*), prior knowledge is considered in the form of a nondegenerate probability distribution of lot proportion nonconforming. This approach is difficult to understand for practitioners, and is theoretically controversial. In fact, for a given lot the actual proportion nonconforming p is a fixed, but unknown, number. Therefore, it is more appropriate to represent prior knowledge on p by an interval $I = \{p \mid p_1 \leq p \leq p_2\} \subset [0; 1]$, which includes the fixed, but unknown, actual value of the proportion nonconforming. If the interval contains only one element, i.e., $I = \{p^*\}$, then the actual proportion is known, while the case $I = \{p \mid 0 \leq p \leq 1\}$ stands for the case that nothing is known about the actual proportion nonconforming.

Sampling-based measurement procedures to determine the unknown value of a proportion nonconforming, under prior knowledge represented by an interval $I \subset [0; 1]$, have been developed in [10]. The procedures are made available on a CD-ROM and can be used straightforwardly without the need for sophisticated calculations.

Measurement of Process Parameters

In modern industrial environments, plenty of data on the lot generating process are available. Such process data should be used for developing a stochastic process model. A stochastic model as introduced by [11] establishes a relation between the indeterminate process output on the one hand and variables representing the physical nature of the process on the other. Because the physical conditions

of the lot generating process are generally not known exactly, the stochastic model includes not only one probability distribution, but a set of potential probability distributions of the process output. If by means of the stochastic model it can be proved that the proportion nonconforming in a generated lot is satisfactorily small, then it is more efficient not to control lot quality directly by measuring the proportion nonconforming in the lot. Instead, sampling should be used regularly for measuring the actual values of the relevant process parameters to exclude process disturbances, which may spoil the lot quality. The necessary stochastic measurement procedures are introduced in [12].

Selection of the Measurement Target

The measurement target of a sampling procedure is either a lot quality parameter, e.g., lot proportion nonconforming, or parameters of the lot generating process.

Lot parameters should be chosen as the measurement target in the following cases: (a) there is insufficient knowledge on the lot generating process and no stochastic process model is available; (b) an available stochastic model for the lot generating process indicates unsatisfactory process quality.

The choice of process parameters as measurement targets requires the availability of a stochastic model for the lot generating process. Under this provision, process parameters should be focused on in the following cases: (a) the process model indicates satisfactory process quality; (b) the required degree of measurement accuracy is very high. In this case, the sample size in pure lot quality measurement procedures as described above is uneconomical.

Future Principles for SPI

The analysis of the preceding sections implies that the following principles in the theory and practice of SPI will be useful in modern industrial environments:

1. Define SPI as a subordinate tool in a product control scheme based on provision and prevention.
2. Make use of the quality relevant information that is available in modern product control. In particular, make use of information on the product generating process.
3. Develop and implement SPI schemes that are adaptive to varying degrees of quality and that are able to switch to the no-sampling alternative.
4. Integrate precise and substantial economic reasoning into the design of SPI schemes.
5. Develop and implement SPI schemes for the control of high-quality products.
6. Consider SPI as tool for acquiring information on quality. Develop procedures to measure the actual values of lot and process parameters reliably and accurately.
7. Abandon the use of MIL-STD and its national and international derivatives. These standards are obsolete, since they have no sound theoretical foundation and do not conform to any of the above principles (1) through (6).

ELART VON COLLANI AND RAINER GÖB

Sampling Inspection of Products and Statistical Process Control

Introduction

Acceptance sampling and statistical process control (SPC) are the most frequently used methodologies of statistical **quality control** (SQC). In acceptance sampling, the result of evaluation of a random sample taken from a group of products (a *lot*) or services is used for making decisions about these products or services. Therefore, acceptance sampling is aimed at product or service disposition decisions, based on statistical testing of stated quality requirements. As opposed to classical acceptance sampling, **control charts**, the best-known tools of SPC, are used to find whether monitored processes are in a “state of statistical control”. In other words, control charts are primarily used as a management tool to verify process stability. For this application of control charts any quality requirements need not be taken into account.

For industrial practice, the aspect of satisfying quality requirements is at least as important as guaranteeing process stability and eliminating sources of process variation. *Acceptance control charts*, introduced by Freund [1, 2], combine features of acceptance sampling and control charts, i.e., they can be used both for monitoring process stability and for verifying compliance with product or service quality requirements. Compliance with quality requirements is a separate issue, which has to be considered on equal footing with the interest of eliminating all sources of process variation. Quality requirements may be satisfied in the presence of small shifts of the process level around its target values. For example, if uniform large batches of raw material are used during a production process, the differences between the process levels related to between-batches variability may be tolerable. Similarly, small infrequent and irregular shifts of the process levels that cannot be eliminated because of economic or engineering (possibility of “overcontrol” of the process) considerations may be tolerated if their impact on the quality of the product is negligible.

Acceptance Control Charts: Design and Operation

The design principles, and the operation of acceptance control charts, have been described in the international standard ISO 7966 [3]. The standard considers the acceptance control of a process characterized by observations X_i , normally considered as continuous measurements, where the procedures can also be used for discrete variables like conforming/nonconforming indicators. It is assumed that there exist two characteristic process levels. The acceptable process level (APL) represents a process that should be accepted almost always, with probability $1 - \alpha$. On the other hand, the rejectable process level (RPL) represents a process that should almost never be accepted. When the process operates at the RPL level, or worse, the probability of its acceptance should be not greater than β . Thus, any process centered between the target value and the APL will have a risk smaller than α of not being accepted. On the other hand, the risk of acceptance of processes located further away from the target value than the RPL is smaller than β . The process levels lying in an “indifference zone” between the APL and RPL yield products of borderline quality. From the point of view of quality control, this “indifference zone” should be as narrow as possible. Unfortunately, the narrower this zone, the larger the **sample size** will have to be. Therefore, some economic considerations have to be present in the design process of acceptance control charts.

To operate an acceptance control chart it is necessary to define two additional parameters: the sample size n , and the action criterion or acceptance control limit (ACL). If the sample average value of the quality characteristic $\bar{X}$, plotted on an acceptance control chart, falls beyond ACL (i.e., above the upper acceptance control limit ACL_U or below the lower acceptance limit ACL_L , in case of double specification limits) the process shall be considered nonacceptable. The location of the APL and RPL levels, and the ACL limits is presented in Figure 1.

In the case of two-sided specifications the process levels APL and RPL are located above and below the target value (see Figure 1). When the APL and α , and RPL and β are defined, the upper and lower

2 Sampling Inspection of Products and SPC

Figure 1 Basic elements of the acceptance control chart

ACLs are calculated as

$$ACL_U = APL_U + \left(\frac{y_{1-\alpha}}{y_{1-\alpha} + y_{1-\beta}} \right) \times (RPL_U - APL_U) \quad (1)$$

and

$$ACL_L = APL_L - \left(\frac{y_{1-\alpha}}{y_{1-\alpha} + y_{1-\beta}} \right) \times (APL_L - RPL_L) \quad (2)$$

respectively. The values of $y_{1-\alpha}$ and $y_{1-\beta}$ are the **quantiles** of the standard **normal distribution** of order $1 - \alpha$ and $1 - \beta$, respectively. The formulas for the calculation of the upper and lower ACLs remain the same in the cases of one-sided specifications or asymmetrical quality requirements. For the calculation of the sample size n , it is necessary to know the value of the standard deviation σ_w within the sample (rational subgroup), i.e. the standard deviation of the measured quality characteristic X , which describes its inherent and natural variability. The value of n is obtained by rounding-up to the nearest integer the value calculated from the following expression

$$n = \max \left\{ \left[\frac{(y_{1-\alpha} + y_{1-\beta})\sigma_w}{(RPL_U - APL_U)} \right]^2, \left[\frac{(y_{1-\alpha} + y_{1-\beta})\sigma_w}{(APL_L - RPL_L)} \right]^2 \right\} \quad (3)$$

Let p_0 be the acceptable fraction of nonconforming items, at the output of the process, and p_1 be the rejectable fraction of nonconforming items. If these two values are known from economic considerations, and the values of the lower specification limit (LSL) and the upper specification limit (USL) are given, we can calculate the values of APL and RPL from the following formulas:

$$APL_U = USL - y_{1-p_0}\sigma_w \quad (4)$$

$$APL_L = LSL + y_{1-p_0}\sigma_w \quad (5)$$

$$RPL_U = USL - y_{1-p_1}\sigma_w \quad (6)$$

$$RPL_L = LSL + y_{1-p_1}\sigma_w \quad (7)$$

The formulas given above are valid when the quality characteristic is normally distributed. In cases of other probability distributions the quantiles of the standardized normal distribution should be replaced with the respective quantiles of the standardized versions of those distributions.

Example

Bottles of nominal value of 1000 cm^3 are filled with sunflower oil. It has been verified that the amount of oil in a bottle is described by the normal distribution. The filling process is considered acceptable if less than 1% of the bottles does not meet the requirement described by the LSL of 995 cm^3 and USL of 1005 cm^3 . The process is considered nonacceptable if the percentage of the bottles that does not meet these requirements exceeds 5%. The standard deviation σ_w , estimated from historical data, is equal to 1.5 cm^3 . The risks α and β are set at the same value, 0.05.

To design the appropriate acceptance control chart we have to do the following computations:

Step 1. For $p_0 = 0.01$ we have $y_{0.99} = 2.326$ and $y_{0.96} = 1.751$.

Step 2.

$$APL_U = 1005 - 2.326 \times 1.5 = 1001.51 \quad (8)$$

$$APL_L = 995 + 2.326 \times 1.5 = 998.49 \quad (9)$$

$$RPL_U = 1005 - 1.751 \times 1.5 = 1002.37 \quad (10)$$

$$RPL_L = 995 - 1.751 \times 1.5 = 997.63 \quad (11)$$

Step 3. The ACLs are calculated as follows:

$$ACL_U = 1001.51 + \left(\frac{1.645}{1.645 + 1.645} \right) \times (1002.37 - 1001.51) = 1001.94 \quad (12)$$

$$ACL_L = 998.49 + \left(\frac{1.645}{1.645 + 1.645} \right) \times (998.49 - 997.63) = 998.06 \quad (13)$$

Step 4. The initial calculation of the sample size gives

$$n = \left[\frac{(1.645 + 1.645) \times 1.5}{1002.37 - 1001.51} \right]^2 = 3.128 \quad (14)$$

Thus, the required sample size is $n = 4$.

Discussion

The acceptance control charts presented in this article are practically the same as acceptance sampling plans by variables. As a matter of fact, popular acceptance sampling plans by variables, presented in the international standards from the series ISO 3951 (see, for example, ISO 3951-1 [4]) should be rather

used to accept (or reject) process levels expressed in terms of fraction nonconforming and labeled by acceptance quality limits (AQLs), than to accept (or reject) individual lots of products. Accordingly, individual sampling plans from these standards could be used for the purpose of SPC. For example, the economically optimal control chart, based on the sampling plans taken from [4] (for unknown values of the standard deviation σ) is proposed by Hryniewicz [5].

OLGIERD HRYNIEWICZ

Sampling in Pharmaceutical and Chemical Industries

Introduction

There are some characteristics of the pharmaceutical and chemical industries that make a difference on how sampling inspections are performed. The product characteristics are given by biological, chemical, and physical measurements. It is often related to batch production. At least for the pharmaceutical industry they are often highly regulated by government authorities with high demands on quality standards and level of documentation.

The measurement methods being used include both slow and expensive off-line methods and fast and cheap on-line measurements. The trend in these industries is that more of the fast and cheap on-line methods become available and to some extent replace the off-line methods. This also means that larger sampling and data evaluation becomes an integrated part of sampling inspection and batch release.

The US Food and Drug Administration (FDA) has recently launched a “process analytical technology (PAT) initiative” supporting this development, see [1]. A desired goal of the PAT framework is to design and develop processes that can consistently ensure a predefined quality at the end of the manufacturing process. Such procedures would be consistent with the basic tenet of quality by design and could reduce risks to quality and regulatory concerns while improving efficiency. Gains in quality, safety, and/or efficiency vary depending on the product and are likely to come from the following actions:

- reducing production cycle times by using on-line measurements and controls;
 - preventing rejects, scrap, and reprocessing;
 - considering the possibility of real-time release;
 - increasing automation to improve operator safety and reduce human error;
 - facilitating continuous processing to improve efficiency and manage variability
- using small-scale equipment (to eliminate certain scale-up issues) and dedicated manufacturing facilities,

- improving energy and material use and increasing capacity.

There are obviously large benefits to gain from this development for the customers in terms of quality, safety, and cost. There will still be a need to perform off-line measurements and classical sampling inspection and release testing in the pharmaceutical and chemical industries as there may be no alternative.

Sampling under Measurement Uncertainty

Sampling of discrete items in lots for inspection is mainly used in the medical device part of the industry. Figure 1 is an example of a person with diabetes injecting himself with a prefilled insulin pen. The example illustrates the critical environment for certain medical products, hence the need for documented high quality products. This is why, for this part of the industry, there may be a specific need for taking measurement uncertainty into consideration.

Sampling plans for inspection by attributes are given in the ISO standard series ISO 2859 [2]; and similar plans for inspection by variables are given by the ISO standard series ISO 3951 [3]. It is a general idea – at least among statisticians – that sampling by variables is a more efficient procedure for **acceptance sampling**, than sampling by attributes. This idea is supported by the fact that under a correct model, a parametric estimator of the fraction nonconforming is

Figure 1 Person with diabetes injecting himself with a prefilled insulin pen

more efficient than the nonparametric estimator based upon the crude count of nonconforming items in the sample.

In industrial praxis, an important issue is the presence of measurement errors. In the measurement situation, the ideal situation is of course that measurement errors are negligible compared to the tolerance interval of the item to be measured. This is not always the case, though. For medical devices there are often high requirements on certain critical parameters, e.g. the dosing accuracy. This again leads to high requirements on the individual components in the tolerance stack up. Both the ISO standards mentioned before [2, 3] consider the case of negligible measurement errors. Therefore, in the following, we shall discuss the implications of using acceptance sampling by variables under measurement error.

The theory for acceptance sampling by variables under a **normal distribution** dates back to the papers by Lieberman and Resnikoff [4] and [5]. The current ISO standard with sampling plans, ISO 3951 [3], is based upon this original idea of basing the test upon a minimum variance, unbiased estimate of the fraction nonconforming in the process. A description of the theory may be found in [6].

In [7], Owen and Chou, consider the effect of measurement error and a constant offset error on the operating characteristic (OC) curves (*see Single Sampling by Attributes and by Variables*) of the one-sided plans. In [8], Thyregod and Melgaard, however, extend these considerations to the double-sided plans in the case of measurement error and a random “laboratory” **bias**.

We shall assume that items in a lot are produced from an in-control process. Let X denote the quantity of interest. We shall assume that the distribution of X over the items in a lot may be described by independent and identically distributed (i.i.d.) random variables that follow a normal distribution with mean $E(X) = \mu$ and $V(X) = \sigma^2$. It should be noted, that in pharmaceutical and chemical processes the assumption of independent items in a lot often must be challenged. Simple graphical methods such as plotting the items in the order of production will often reveal correlations that must be taken into account.

Let the specification limits for X be upper limit, U , and lower limit, L , respectively. The fraction of nonconforming items, p , is the fraction of items below L or above U . In the related article **Variables Sampling under Measurement Error** the case of

high-frequency measurement error is discussed in detail.

High-Frequency Measurement Error

Assume that the quantity of interest cannot be measured without measurement error.

Let $Y = Y(X)$ denote the measurement result for an item with value X . Assume that

$$Y_i = X_i + E_i \quad (1)$$

where $E_1, \dots, E_n$ are i.i.d. and normally distributed with $E(E_i) = 0$ and $V(E_i) = \sigma_e^2$. Let, as usual,

$$\bar{Y} = \sum \frac{Y_i}{n} \quad (2)$$

and

$$s_y^2 = \sum \frac{(Y_i - \bar{Y})^2}{(n-1)} \quad (3)$$

Then $\bar{Y}$ follows a normal distribution with $E(\bar{Y}) = \mu$ and $V(\bar{Y}) = (\sigma^2 + \sigma_e^2)/n$, and s_y^2/σ^2 follows a $(1 + \sigma_e^2/\sigma^2)\chi^2(f)/f$ distribution with $f = n-1$, and $\bar{Y}$ and s_y^2 are independent. For simplicity we will use the OC curves, corresponding to the one-sided plans, which are similar to the ones given in ISO 3951. These will be close to the double specification limits case, when $\sigma \ll \sigma_{\max}$. It is shown in [8] that by using the same sampling plan from ISO 3951 – but in this case random measurement error is present – according to the model (1) the **OC curve** is given by

$$L_1(p) = P \left\{ \frac{U - \bar{Y}}{s_y} \geq k \right\} = P\{t_{n-1, \delta_1} \geq k\sqrt{n}\} \quad (4)$$

where $\delta_1 = -\sqrt{n}z_p/\sqrt{1 + \sigma_e^2/\sigma^2}$. One thing to remark is that the OC curve in the case of random measurement noise is always to the left of the noise-free OC curve, which means that in the case of high-frequency measurement noise; there is a higher chance of rejecting the batch. An example from ISO 3951 is given by Figure 2.

Low-Frequency Measurement Error

Assume instead that the major part of the measurement error is a random “laboratory” or instrument bias that affects all measurements in the same manner, i.e.

$$Y_i = X_i + B \quad (5)$$

Figure 2 OC curves under high-frequency measurement error, $AQL = 6.5$, code K, $n = 50$, $\sigma_e = 0.2\sigma$, the dashed curve is for the model without measurement error

Figure 3 OC curves under low-frequency measurement error, $AQL = 6.5$, code K, $n = 50$, $\sigma_B = 0.2\sigma$, the dashed curve is for the model without measurement error

where B varies from lot to lot as i.i.d. and normally distributed with $E(B) = 0$ and $V(B) = \sigma_B^2$. Under this assumption we have that $\bar{Y}$ follows a normal distribution with $E(\bar{Y}) = \mu$ and $V(\bar{Y}) = \sigma_B^2 + \sigma_e^2/n$, and s_y^2/σ^2 follows a $\chi^2(f)/f$ distribution with $f = n - 1$, and $\bar{Y}$ and s_y^2 are independent. Thus, in this case the uncertainty of the estimate, $\bar{Y}$, of the position, is heavily influenced by the measurement uncertainty, but the estimate, s_y^2 of the process spread is not affected.

The OC curve for this model is then given by

$$\begin{aligned} L_2(p) &= P \left\{ \frac{U - \bar{Y}}{s_y} \geq k \right\} \\ &= P \left\{ t_{n-1, \delta_2} \geq \frac{k\sqrt{n}}{\sqrt{1 + n\sigma_B^2/\sigma^2}} \right\} \end{aligned} \quad (6)$$

where $\delta_2 = -\sqrt{n}z_p/\sqrt{1 + n\sigma_B^2/\sigma^2}$. If we let

$$n_* = \frac{n}{1 + n\sigma_B^2/\sigma^2} \quad (7)$$

in the equation for $L_2(p)$ we see, that the equation is very close to the noise-free one, but with a **sample size** of n_* . The only difference is that the **degrees of freedom** in the t distribution are not changed. This means, that approximately the OC curve in case of a systematic measurement error is similar to the OC curve of the noise-free case, but with a reduced sample size.

In the example given by Figure 3, we have a sample size of $n = 50$ and a measurement uncertainty of $\sigma_B = 0.2\sigma$. Approximately this corresponds to the OC curve of the noise-free case with a sample size of

$$n_* = \frac{50}{1 + 50(0.2)^2} = 16.7 \quad (8)$$

This fact is also revealed from Figure 3. It is important to notice the difference between the noise-free case and the situations with high-frequency as well as low-frequency noise. Especially for testing in the pharmaceutical and chemical industries the measurement uncertainty is not negligible. This requires that the measurement method is well documented, including quantification of the high- and low-frequency measurement error. Since the influence of a low-frequency measurement error can be large, as shown in the previous example, steps will normally be taken to minimize this effect, e.g. by calibrating between sampling of lots.

Bulk Sampling

Purpose and Procedure of Bulk Sampling

Chemical analyses of bulk materials as powder or liquids are often found in the pharmaceutical and chemical industries by its nature. Sampling can be used for the inspection of raw materials, intermediate products, or final product release. In this case a lot is a definite quantity of bulk material. The quality

of the lot is measured by a single suitable quality indicator, e.g. the content of active ingredient. It is assumed that the mean quality of the lot is to be determined and that this is the factor used for determining the acceptability of the lot. In this case, acceptance sampling plans and procedures for the inspection of bulk materials are found in ISO 10725 [9].

A number of increments (smaller volumes), k , of the same size are taken randomly from the lot. These increments are mixed into a gross sample. From this gross sample a laboratory sample is prepared and a number of samples, m , is taken from this laboratory sample and analyzed individually. The results, x_i , $i = 1, \dots, m$, are combined into a single mean value that is representative of the lot. The mean value of the analyzed samples is used as the estimate of the mean quality of the lot. The mean is calculated as

$$\bar{x} = \sum_{i=1}^m \frac{x_i}{m} \quad (9)$$

The uncertainty (variance) of this mean value is given by

$$V(\bar{x}) = \frac{\sigma_A^2}{k} + \sigma_B^2 + \frac{\sigma_C^2}{m} \quad (10)$$

where

- σ_A^2 is the variance of the increments from the bulk due to variations between containers and within containers,
- σ_B^2 is the variance associated with the preparation of the laboratory sample taken from the gross sample,
- σ_C^2 is the variance describing the uncertainty from preparing and analyzing the individual samples for analyses taken from the laboratory sample.

The model above is a simple statistical model describing the bulk sampling situation. To have a “statistical rationale” for the choice of k , the number of containers to sample from, and the choice of m , the number of chemical analyses to perform, some estimates of the **variance components** must be found, e.g. from designed statistical experiments, see [9].

Retesting of Bulk Materials

Retesting is when new laboratory samples are taken from the gross sample of a lot to be analyzed because

of suspicious analytical results. For specific chemical or biochemical laboratory analysis, a large number of steps are involved and the analyses are not always fully automated. In these cases there is a possibility of occasional (human) errors affecting the results. Therefore, there are well-described procedures for good manufacturing practice (GMP) including procedures for handling out-of-specification (OOS) measurement results, see [10]. In the case of discrete items handled in the section titled “Sampling under Measurement Uncertainty”, the ISO standards have built-in procedures on how to handle the situation of OOS results and batch rejection.

The procedure [10], applies to laboratory testing. It applies to the situation described previously where the mean quality of the lot is of interest. It does not apply if the purpose of the analyses is to measure uniformity of a lot, e.g., content uniformity, release profile, and powder blend.

To identify the cause of the OOS result, statistical **hypothesis testing** may be relevant. Hypothesis testing may consist of repetition of the test procedure or part of the procedure, or of experiments designed specifically with the purpose of identifying an analytical problem. Below is an example of retesting.

Use of t -Test to Compare OOS Results and Retest Results.

The t -test is appropriate in a retest situation where an OOS result is compared to a group of results obtained specifically, to compare it to the earlier result, as described by Søren Andersen [11]. The test statistic is given by

$$T = |OOS - m_{\text{retest}}| / (s_{\text{retest}} \sqrt{(1 + 1/m)}) \quad (11)$$

where m_{retest} and s_{retest} are the mean and standard deviation of the retest results and m is the number of retests. The retest samples should be representative of the lot being sampled, i.e., use the gross sample from the previous test or create a new gross sample based on increments randomly taken from the lot. The calculated test statistic, T , is compared to the critical value of the t -test, given e.g., in [11]; if T is greater than the 5% critical value, the OOS is considered a statistical **outlier**. If the OOS result is considered a statistical outlier, we have a strong indication that the result is due to a laboratory error. A qualified person should then be able to evaluate the necessary steps to eventually release the batch.

Sampling in Semiconductor Manufacturing

Introduction

A state-of-the-art complementary metal oxide semiconductor (CMOS) manufacturing process combines a myriad of transistors connected by several metalization layers on a tremendously small area. This is achieved by several hundred processing operations, i.e., each being a physical treatment on processing equipment. The processing results are verified with certain types of metrology. For an overview refer to [1, 2] and references therein. Typical metrology applications are:

- defect inspection (visual, microscope)
- critical dimension scanning electron microscope (SEM) measurement
- overlay registration measurement
- thickness measurement using ellipsometry
- step height and profile measurement using profilometers, atomic force microscope (AFM), and scatterometry
- electrical tests on test structures (e.g., single resistors or transistors, ring oscillators).

Since semiconductor manufacturing is performed in clean-room environments, the available floor space for process and especially metrology equipment is limited. Furthermore, a high production line throughput with low cycle times enforces tight metrology budgets. Consequently, sampling is about balancing metrology objectives and constraints.

Examples: (a) A very stable and established process step may receive only moderate defect inspection and loose parametric control. This may apply in a proved process to a hydrofluoric (HF) clean or a furnace- poly-silicon deposition. (b) Conversely, a very critical process step, which may even operate on a novel tool platform, must be followed by several metrology steps, with very high sampling rates. This may, for example, apply to the whole gate formation process sequence.

A typical semiconductor manufacturing scenario is grouping several (e.g., 25), silicon wafers into lots and processing them at a processing operation.

Whenever a metrology inspection is performed only a subset of its wafers, and of course, only certain positions on a wafer, receive the metrology inspection.

The structure of the sampling decision depicted by Figure 1 is organized as follows:

(a) Select a lot, (b) pick wafers within the lot, and (c) decide for positions on the wafers. The three levels of a sampling decision are denoted by *lot sampling*, *wafer sampling*, and *site sampling* in the following text.

In modern 300-mm manufacturing, the actual task of sampling must be fully automated in order to practically account for the huge number of influencing variables.

This means that the tasks have to,

1. make the sampling decision;
2. dispatch and transport the lot to a metrology station;
3. select the to-be inspected wafers and the metrology recipe (to-be measured features and their positions);
4. start the inspection process on the metrology equipment;
5. acquire the measured data;
6. provide measured data to attended customers (e.g., **statistical process control** (SPC), advanced process control (APC), data mart, etc.);
7. remove the lot from metrology station.

These tasks are performed completely automatically by state-of-the-art MES (manufacturing execution system), EI (equipment interface), and other FAB (fabrication plant for semiconductor manufacture) automation and IT (information technology) infrastructure. The above tasks and their application

Figure 1 Structure of sampling decision

2 Sampling in Semiconductor Manufacturing

on the manufacturing floor do, nonetheless, allow human intervention and may in certain cases still require human interaction.

The subsequent paragraphs discuss in more detail the task 1 – to make the sampling decision.

Sampling Decision

State-of-the-art semiconductor manufacturing depends on relevant metrology data in order to monitor and maintain the process, thereby minimizing the risk of processing errors/faults. The term *relevant data* is directly linked to the sampling decision, which has to provide a representative part of a population for the purpose of determining parameters or characteristics of the whole population [3, 4]. The decision process itself is restricted by certain expense criteria. In conclusion, sampling has to select the appropriate material for metrology based on manufacturing needs (also known as *metrology objectives*) while fulfilling manufacturing constraints (also known as *metrology cost*) [5].

Metrology Objectives

Typical state-of-the-art semiconductor manufacturing sampling follows the metrology objectives given below, with the goal to minimize the risk for misprocessing:

- A1. Reconfirm correct processing after wafer-external production disturbance, i.e., logistic (e.g., **preventive maintenance**, tool repair), or manufacturing (e.g., batch changes, recipe adjustments).
- A2. Reconfirm correct processing after wafer-intrinsic production disturbance, e.g., detected processing faults (after metrology or sensor signal) should trigger verification metrology for affected lots/wafers to decide about further steps like rework or even wafer scrap.
- B1. Maintain correct processing by detecting unexpected disturbances, i.e., measure regularly, all suspected sources of variation like entity, process recipe, product, processing order, and used chambers.
- B2. Maintain correct processing by detecting expected disturbances, i.e., provide data to quantify control adjustment by (a) measuring

regularly (static), all sources of variation that are known/modeled and (b) adapting (dynamic) to the needs in case of performance issues.

- C. Reconfirm correct processing according to particular request, e.g., external customer request, or engineering request.

The elements defining a specific abstract metrology objective are denoted as *context elements* in the following text. Typical context elements are (a) on lot level: equipment, preventive maintenance, product; (b) on wafer level: used chambers, defect count; and (c) on-site level: wafer zone, site signature.

Metrology Constraints

Besides the aim to minimize the risk, sampling is also about minimizing the cost for metrology. Metrology expense factors are:

- A. Individual lot cycle time limitations, e.g., wafer-carrier transportation, idle state of non-inspected wafers.
- B1. Metrology acquisition expenses, e.g., tool, clean-room floor space, supply/waste facilities.
- B2. Metrology operating expenses, e.g., service, maintenance, **calibration**, **power** supply.
- C. Metrology capability limitations, e.g., wafer contamination with particles/deposits, destruction of test structures by metrology itself.

Sampling Decision Process

Metrology objectives are imposed by the risk of misprocessing while metrology constraints are defined by certain budgets. The key purpose of sampling is to balance these two opposed factors, i.e., to minimize the risk of misprocessing at tolerable metrology expenses. Therefore, the sampling decision should incorporate a weighting of the metrology objectives, e.g., by organizing them in a hierarchical structure.

Furthermore, it cannot be assumed that any subpopulation of context elements is independent and identical; thus a simple arrangement of context elements is not sufficient.

This leads to additional complexity beside the hierarchical structure, because the sampling decision must also incorporate dependencies among context elements.

The sampling decision is the more optimal, the more simultaneous metrology objectives can be met

Figure 2 Sampling system overview

at once. The decision system must, therefore, detect and actively create such coinciding situations. This enables the possibility of low sampling rates, which also means low metrology cost, while achieving best risk mitigation.

In principle, the sampling decision lot/wafer/site is achieved by connecting lot/wafer/site context elements to sampling rules, e.g., a fixed minimum sampling rate (objectives B), or forced metrology (objectives A). Thereby, the ability to mix the granularity (lot/wafer/site) of sampling decision and metrology objective is a must, e.g., a site-level metrology objective may trigger the decision on lot level. However, even a coarser granularity, i.e., focusing on a batch of lots can be practical and needed.

The sampling decisions with respect to lots, wafers, and sites differ in nature. The lot sampling decision is binary in its result. A lot can either receive metrology or not, mostly independently, from other lots or affected wafers/sites owing to its associated high metrology cost on lot level, e.g., transport. Since the incurred cost of measuring additional wafers in many semiconductor metrology applications is small, the wafer sampling task is mostly to pick the optimal wafers satisfying many metrology objectives at once. Basically, site sampling specifies which feature should get measured at which position of a wafer. Thereby, the term “feature” denotes a subtask or sub-recipe of a metrology recipe. It should be mentioned that most current semiconductor metrology tools do not currently support automatic position and/or feature selection. Actual state-of-the-art site sampling means selecting predefined metrology recipes which serve specified metrology objectives.

Implementation of Sampling

An example for a state-of-the-art sampling solution is presented schematically in Figure 2 and will be denoted as *sampling system*. The sampling system provides a framework that has the capacity to:

- incorporate weighing of the metrology objectives;
- incorporate dependencies among context elements;
- incorporate complexity in a reasonable way;
- choose the appropriate lots and pick the optimal wafers/sites.

In general, engineering knowledge is crucial in order to specify the metrology objectives. Therefore, an integral part of the sampling system is a kind of content management system providing the ability to easily and transparently specify the high-level metrology objectives. Furthermore, the sampling system is linked to SPC systems in order to verify metrology results [6].

Lot Sampling

Of course, in order to end up with acceptable overall sampling rates, the system requires some degree of freedom. The metrology objectives (context elements) determine the *sampling rules* that are applied to the lots. Among the sampling rules that can be applied the most common ones are (a) Simple sampling rules like “measure 30% according to a deterministic pattern”. (b) Check explicitly for metrology gaps only, e.g., number of lots not measured or a

4 Sampling in Semiconductor Manufacturing

certain time window. (c) Flexible sampling rules targeting a certain sampling rate over a period of time.

The sampling system also incorporates a weighing of metrology objectives. For example, assume that objectives A1, A2, and C are associated with high risks, while B1 and B2 are associated with lower risks. The sampling system can weigh an event of objective B1 or B2 with the possibility to achieve lower sampling rates when waiting for a simultaneous event of objective A1 or A2.

The circumstance of incorporating dependencies among context elements is met by the fact that the sampling system is capable of combining arbitrary context elements. This allows, for example, straightforward setup of rules like “critical products” with “latest technology generation” with “suspected tool set”.

In order to incorporate the complexity in a reasonable way, the context elements representing the metrology objectives are organized into a hierarchically structured finite-state automaton. The automata approaches are known to be very well suited for computer simulations and have therefore become quite popular in various fields [7–9]. Thus, all the above objectives are organized into simple local rules reproducing the complex sampling tasks by their dynamical interaction.

The following is a typical lot sampling example from lithography. It illustrates how the sampling

system reconciles multiple overlapping rules with the fewest possible measured lots. Assume that the metrology objectives are:

- A1. Measure the next lots after certain events, e.g., resets.
- A2. Consider particular lots, e.g., rework, yield learning or development.
- B1. Ensure a minimum sampling rate as follows: monitor (a) the process entity, (b) the combination of process entity and operation, and (c) the product, i.e., AMD Opteron, each with an individual baseline and minimum sampling rate of $X\%$.
- B2. Consider APC application performance.

Figure 3 shows that the sampling system is able to achieve a reduction in the overall sampling rate of more than 20% relative to an additive sampling approach. The sampling rate (simulated) of an additive approach is represented by the tallest bar. However, the effective sampling rates established by the sampling system are represented by the next three bars, in respect to metrology objectives B1. Note that each of these three bars is a combination of individual sampling rates setup, e.g., critical operations or entities equipped with higher rates. The remaining bars reflect how often the rules connected to the above metrology objectives, i.e., A1, A2, B2, and minimum

Figure 3 Lot sampling example

Figure 4 Wafer sampling example

sampling rates of B1, have become active. They further illustrate that the balancing among the sampling objectives works quite well, e.g., the rule requiring a minimum sampling rate on the process entity already ensures that the combination of process entity and operation, or measurement of AMD Opteron product is mostly satisfied.

Wafer Sampling

The wafer sampling task, to pick the best wafers satisfying the metrology objectives, is hard to satisfy, considering the tight metrology budgets. In general, it is not possible to comply with all metrology requirements at every metrology step, in the sense that all wafers can receive metrology. To solve this problem all rules are assigned with a certain penalty. A mixed integer linear program (MILP) is used to minimize the number of selected wafers according to the assigned penalties [10, 11]. The penalties can also be increased after rule violation in order to satisfy all requirements with a finite frequency in course of time.

An example of wafer sampling is given in the following text. Assume that the metrology objectives are B1 to monitor all used chambers and B2 to prefer

the last processed, meaning most likely contaminated wafers (highest slots).

In Figure 4 the results for wafers selected by the sampling system are depicted for the given example. Each column represents a single lot consecutively (x axis) processed on a two-chamber tool (CH1, CH2) at a certain process operation. The symbols within a column represent the wafers within a lot positioned at a certain slot (y axis). A filled symbol corresponds to a selected wafer and the chambers where the wafers were processed are distinguished by the shading. It can be seen that the wafer sampling systems picks both chambers (two wafers), if possible (objective B1), and prefers the last wafer processed (objective B2). The last wafer processed, is always one that is positioned in the highest slot.

Assuming that as a further restriction, only one wafer may be selected per metrology run, the algorithm would decide to pick both chambers alternating, if equipped with the same penalty.

Site Sampling

Finally, the site sampling task has to be performed for the wafers selected. This is organized as follows:

(a) selection of the appropriate metrology recipe for a wafer, e.g., standard short recipe or special long recipe; (b) selection of the metrology features to be performed for the chosen recipe; and (c) selection of the metrology sites (positions) where the features have to be performed. Comparable to lot Sampling (a), (b) and (c) are determined by context elements and may also be connected to sampling rules, e.g., perform standard recipe for 90% of wafers while for 10% the special recipe is performed. As mentioned before, most current semiconductor metrology tools do not currently support automatic position and/or feature selection. The site selection process is, therefore, often reduced to an automated recipe selection.

Sampling in Software Development

Introduction

Sampling inspection in software development is more theory than practice. Surveys have shown that the use of quantitative **quality management** methods is scarce in industry [1, 2]. However, the theory is quite well established, and some examples of successful use exist. This article first gives a short historical perspective on quality control in software engineering. Then we elaborate on the use of sampling in software inspection and software testing, and focus on **estimation** of fault content and failure behavior.

Statistical Quality Control in Software Development

In the software sector, the focus of sampling and statistical quality control is on the *development* process, while in areas of physical products, the *production* process is the main focus. The production of software is trivial, i.e., copying some electronic files to a storage medium, while software development involves handling the inherent properties of software, defined by Brooks as, (a) it is more complex than any other construct of its size, (b) it must conform to arbitrary interfaces, (c) it is subject to constant change, and (d) it is invisible [3]. These challenges have led to the need for defining and adding support to the software development process.

The use of **statistical process control** in software development has its roots in the late 1960s. At the NATO conference in Garmisch-Partenkirchen 1968, the term *software engineering* was launched, which was later defined as “the application of a systematic, disciplined, quantifiable approach to the development, operation and maintenance of software; that is, the application of engineering to software” [4].

Winston Royce’s seminal paper, presenting the waterfall development process model [5], was an initial step toward software quality management. Royce also proposed the process being iterative, a concept further developed by Basili [6]. Mills’ Cleanroom method, which was developed at IBM during the 1960s is based on iterative processes

and focuses on the statistical quality control [7], applying inspection and sampling-based testing to assess the software quality. The concepts of iterative development have gradually moved into practice in industry, while the statistical quality control is less widespread, although approaches to adopt statistical process control to software development exist [8] and have been revitalized in the context of agile software development [9].

In this article, we define software *failures* as externally observable misbehavior, encountered during execution. Software *faults* (or defects) are the internal phenomena, statically residing in the code or another artifact. *Error* is a human action resulting in a fault. Errors committed during development may cause a fault in the software code, resulting in a failure during operation [4].

Sampling in Software Inspection

Software inspection is “a static technique that relies on visual examination of development products to detect error, violations of development standards, and other problems. Types include code inspection and design inspection” [4]. The inspected objects can hence be different kinds of documents, specifications as well as code. After an inspection, the number of faults found in the document is known. However, from a management perspective it is more important to know how many faults remain to schedule resources for quality improvement activities and to make release decisions.

Capture–Recapture Technique. The capture–recapture technique was first applied to software inspections by Eick *et al.* [10]. Basically, different reviewers inspect the same document – requirements, design, or code – and report the faults found. On the basis of the overlap between the reviewers’ detected faults, an estimate of the number of remaining faults can be achieved. The simplest model is the Lincoln–Peterson’s estimation model for two reviewers, see equation (1)

$$\hat{N} = \frac{n_1 \times n_2}{m_2} \quad (1)$$

where $\hat{N}$ is the estimate of the total fault population, n_1 and n_2 are the number of faults found by reviewers 1 and 2, respectively, and m_2 is the number of faults found by both reviewers.

2 Sampling in Software Development

Table 1 Capture–recapture models with their respective assumptions and estimators used [2]

Model	Fault probability	Reviewer capability	Estimator
M_0	Equal for all faults	Equal for all reviewers	ML
M_t	Equal for all faults	Different for different reviewers	ML, Chao
M_h	Different for different faults	Equal for all reviewers	Jackknife, Chao
M_{th}	Different for different faults	Different for different reviewers	Chao

There are four principal models, which have different assumptions on the probability for a fault to be found and for the capability of the reviewers to find a fault, see Table 1. The models can be combined with different estimators [2].

Most studies find the M_h -model with jackknife estimator providing most robust estimates, which is natural since it is nonparametric. The research on capture–recapture in software inspection is elaborated in depth by Petersson *et al.* [2].

Sample-Driven Inspection. Sample-driven inspection is an approach to improve the efficiency of the inspection process by concentrating the inspecting effort on those documents that have most faults [11]. This inspection process has four main steps: (a) sampling, (b) preinspection, (c) resources scheduling, and (d) main inspection. A portion of each software document is randomly sampled for preinspection, constituting 10–50% its size, which is a trade-off between the acceptable uncertainty in the prediction and the available resources. The sampled portions are preinspected and the fault content is estimated on the basis of the sample. The documents are then ranked according to the estimate and the remaining inspection effort is spent on the documents with highest ranks according to the fault estimate.

The method is evaluated using **Monte Carlo** simulations by Thelin *et al.* [11], indicating that the method is more efficient than random selection of a subset. Twenty to thirty percent of the document should be preinspection to achieve good resources scheduling. The method is particularly efficient when the quality varies significantly across the documents.

Sampling in Software Testing

Software testing is “an activity in which a system or component is executed under specified conditions, the results are observed or recorded, and an

evaluation is made of some aspect of the system or component” [4]. In contrast with inspection, testing is dynamic, i.e. conducted by executing the software. Hence, only the software code can be verified during testing, and not the requirements and design specifications. Similar to inspection, we want to predict the number of remaining faults after testing. Predicting the operational failure behavior in terms of reliability or mean time between failures is also desirable after testing. A test case is a specific combination of inputs to the program, leading to a predetermined output. To run all combinations is impossible for all but very small programs. Hence, testing is implicit or explicit sampling from the future use of the program.

Different strategies exist for sampling the test cases to execute. Strategies may be functional (also called *black box*, i.e., based only on the externally visible interfaces of a program or component) or structural (also called *white box*, i.e., based on the program structure). The input/output domain or the structure-based domain is split into partitions, which are assumed to have similar properties for a given input. Test cases are sampled from each partition. The test cases may be sampled to cover all the partitions, the most prioritized partitions, or randomly sampled. Which sampling strategy to use is based on its effectiveness in detecting faults, while the ability to estimate faults and predict failure behavior is a secondary goal.

Fault Estimation

To *estimate remaining fault* content, Mills proposed *seeding* additional faults into the code [12]. Faults are seeded before testing, and it is assumed that the sampled test cases reveal the same proportion of original faults as of the seeded faults. The number of remaining faults is estimated using e.g., the Lincoln–Peterson model mentioned above, where

n_1 and n_2 represent found original and seeded faults, respectively. The main problem of this approach is to seed representative faults into the code. The seeding also requires extra effort.

Stringfellow *et al.* [13] applied the capture–recapture techniques to testing at different test sites, testing the same components in parallel. Hence, no extra effort is needed for seeding faults.

Failure Prediction

To predict the operational failure behavior, **software reliability testing** can be used (also called *statistical testing* or *operational profile testing*). The principal idea is that test cases are sampled from a model of the future usage of the software, i.e. selected based on the operational usage frequencies. The failure data from these tests are then employed to fit a software **reliability growth** model [14], thus predicting the operational failure behavior in terms of mean time between failures (MTBF) or reliability based on the sample from testing. The future usage is specified in terms of a usage model, e.g. a list of test cases or features and their corresponding operational usage frequencies.

Different types of usage models are proposed, including domain models [15], Markov models [16], and the operational profile model [17]. Sampling from these models can be conducted with or without replacement [16] and also using stratifying techniques [18]. Various approaches are presented to accelerate the testing without sacrificing the predictive capabilities [19]. However, most reliability models require random sampling from the future usage. Despite decades of research, the state of practice on software reliability testing is rather immature, except in domains of extremely high quality requirements.

The failure data recorded during the test case execution is fit into a software reliability prediction model. There are an extensive number of models proposed in the literature. The two most common approaches are time between failure models and failure count models.

The first *time between failure model* was the Jelinski–Moranda model [20], where it is assumed that the times between failures are independently exponentially distributed. Let X_i denote the time between the $(i - 1)$ th and i th failure, then the **probability density function** of X_i is defined as $f_{X_i}(t) = \lambda_i e^{-\lambda_i t}$. λ_i is assumed to be a function of the

remaining number of failures and is derived as $\lambda_i = \phi(N - (i - 1))$, where ϕ is a constant representing the failure intensity per fault.

Goel and Okumoto proposed a *failure count model* [21] in which $N(t)$ is described by a non-homogeneous **Poisson process**, in which the failure intensity decreases for every fault that is removed from the code. The expected number of faults found at time t is described as $m(t) = N(1 - e^{-bt})$, where N is the total number of faults in the program and b is a constant. The probability function for $N(t)$ is expressed as $P(N(t) = n) = (m(t)^n / n!) e^{-m(t)}$.

A comprehensive overview of software reliability models can be found in [14].

Summary

Sampling inspection can be applied to software development during inspection and testing. The purpose is to find faults and to estimate the number of remaining faults and the operational failure behavior. The theory is quite well established, while the practical application is rare, except in industries with very high quality demands.

Sampling in Data Mining

Data Mining and KDD

Knowledge discovery in databases (KDD) is commonly defined as the *nontrivial process of identifying valid, novel, potentially useful, and ultimately understandable patterns in data* [1, p. 6]. The first step in this process is **data collection**. The collected data are stored in (operational) databases, possibly together with background information (metadata). Usually, the data collected in this manner are noisy and inconsistent, so they have to be cleaned, integrated, and transformed. To make the data available for later analysis in such a form that the adequate information is provided in adequate form and detail, the data are organized in a *data warehouse*. A *data warehouse is a subject-oriented, integrated, time-variant, nonvolatile collection of data in support of the management's decision making process* [2, p. 31], i.e., the data are not organized in transactional form but according to major subjects, providing information over a longer period of time. The warehouse integrates data from different data sources in a cleaned and unique format. It is separated from the operational databases, updated only at certain times such that existing data remains unchanged.

The next step in the KDD process consists in analyzing the data stored in the warehouse. If fast queries are desired, then methods of *on-line analytical processing (OLAP)* are the right choice. It is a widely accepted guideline that OLAP tools should deliver results within about 5 s and be able to deal with multidimensional data. To get deeper insight into the data and to detect complex patterns and regularities from vast amounts of data, methods of **data mining** should be applied. The term *data mining* in the strict sense refers to this analytic purpose only, in a more global sense it is also used as a synonym for KDD as a whole. Data mining methods are much more complex than those of OLAP, with the only restriction that they must be able to handle large amounts of data, usually too large to fit in main memory. In the last step of the KDD process, the obtained knowledge is presented to the user. For more details on KDD and data mining see [3].

In this article, we will investigate the topic of *sampling in data mining*. We begin with a general description of typical situations of sampling, and

continue by discussing techniques of sampling that are commonly used in data mining. Finally, we review various fields of data mining where sampling techniques are applied.

Sampling from Databases: Overview

Sampling approaches are applied to various areas of KDD and data mining. The motivation for sampling in data mining, however, is different from that of sampling in traditional statistics. In the latter case, data are often considered expensive and difficult to collect, while it is available in huge amounts in the case of data mining. In fact, it is a common strategy to collect as much data as possible, with the highest possible dimensionality. As a consequence, one often has too much data to be processed by data mining procedures, and sampling methods have to be used to reduce these amounts of data.

The situation sketched above can be related to the general sampling scheme of Deming [4]. Three levels in the sampling process are distinguished: the basic level is the *cause system*, i.e., the population behind the collected data. The next level is the *lot*, the available data from the cause system. In many situations of KDD, it is reasonable to identify the lot with the data warehouse. From this lot, a *sample* is drawn, which will be analyzed with methods of data mining. If the results obtained are used to estimate the properties of the lot, the data are used for an *enumerative* analysis, if it is used to estimate properties of the cause system, Deming [4] speaks of an *analytic* study. The distinction between both types of problems is important, leading to different sampling errors, for instance. The distinction is also known to the KDD community, where *descriptive* and *predictive* data mining are distinguished [3], although it is not clear whether it is always considered in practice.

Sampling in Data Mining: Techniques

The sampling techniques used for data mining are closely related to standard approaches of statistics. Depending on the purpose of sampling – for more details see the following section – techniques like simple random sampling, with or without replacement and possibly under stratification, are used, as well as **sequential sampling** strategies and cluster

sampling. For a description of these techniques see **Sampling Designs in Surveys**. The terminology of these approaches, however, is often different from that of KDD. Depending on the evaluation condition, for instance, sequential sampling is referred to as *adaptive*, *progressive*, or *dynamic* sampling.

Especially for estimating model performance, techniques of data partitioning are commonly used in data mining. The *holdout method* divides the available dataset of n records into a training and a test set, possibly considering stratification. In *k-fold cross-validation*, the initial data are split into $k \leq n$ disjoint subsets $S_1, \dots, S_k$ of approximately equal size. In each iteration $i = 1, \dots, k$, S_i serves as a test set, the union of the remaining sets as training data. The final result is obtained as an average of the k individual results. A special case is the *leave-one-out method*, where $k = n$ [3, 7.9.1].

Sampling in Data Mining: Purpose

In this section, we will briefly review areas of KDD and data mining, where sampling is used: sampling for data reduction, for algorithm recommendation, for initialization of algorithms, for query optimization, for privacy protection, for model validation, and for generating multiple models.

Sampling for Data Reduction

Data, although possibly collected in transactional form, is usually analyzed in tabular form. The columns of a data table represent the *attributes*, *features*, or *variables*, the rows represent the individual *records*, *instances*, *examples*, or *cases*. The number of features is the *dimension* of the data. The need for data reduction before performing analyses can be due to both the dimension of the data and the number of records. Although sampling is usually used to reduce the number of records, it can also be helpful to reduce the dimensionality of the data. Filter techniques of *feature selection* aim at removing irrelevant features from the data, where the decision about relevance is based on given training data. The training data can be obtained by simple random sampling, but other approaches are also known. Liu *et al.* [5], for instance, describe a strategy called *active feature selection*, which applies a selective sampling strategy for building the training sample. The procedure aims

at selecting those records that are most informative in determining the relevance of features.

The main purpose of sampling in data mining concerns the reduction of the number n of records of a dataset, compare [6]. The run time of data mining algorithms usually grows at least linearly in n . In addition, the data will not fit into main memory if n is larger than a certain upper bound. The process of making procedures able to deal with datasets of growing size n is called *scaling up* of algorithms. In some cases, scaling-up can be done by optimizing the computational complexity of the algorithm, or by using distributed algorithms. Another approach to scaling-up is to reduce the amount of data by sampling. This can be done for one specific analysis only, using a specially designed sampling strategy. An example is the windowing technique for decision tree building, where an initial random sample is replenished with misclassified records of a test set. Or one tries to construct a sample, which is representative for the whole database, i.e., a sample, the main characteristics (distribution, **moments**) of which match those of the database. Representativity is commonly checked by comparing marginal properties like univariate means. Inmon [2] even suggests building a reduced data warehouse, called *living sample data*, where “living” expresses that the database needs to be refreshed periodically. For more details on scaling-up algorithms see [6].

Sampling for Algorithm Recommendation

Given a specific analytical task and a set of potential algorithms, *algorithm recommendation* aims to select a subset of algorithms, preferably of size 1, that are expected to work best on the problem. Therefore, the candidate algorithms are commonly evaluated based on a random sample of the data. An example concerning classification methods is described by Schaffer [7], who proposes the use of cross-validation to determine the method with highest average accuracy.

Sampling for Initialization of Algorithms

Sampling can be applied to determine starting values for learning algorithms, to carry them out more efficiently. Toivonen [8], for instance, applied sampling to association rule mining, where a database of itemsets (“market baskets”) is analyzed for frequent

subsets, i.e. subsets which are contained in at least $s_{\min}$ of all available records. Toivonen [8] suggests application of the algorithm to a random sample first, small enough to fit into main memory, so as to find a superset of the collection of all frequent sets. The whole database is then used to determine the exact frequencies of these specific sets only, resulting altogether in an approximate solution of the problem of detecting all frequent sets.

Sampling for Query Optimization

Sampling can be used to optimize the design of queries before applying them to the complete database. On the basis of the selected random sample, the execution time of the query or the size of the result returned by the query can be estimated. For more details see [9]. This is also an important purpose of the living data sample proposed by Inmon [2], which was discussed above.

Sampling for Privacy Protection

Users of a database are often allowed to perform only aggregate queries like COUNT, SUM, and so on, to prevent them from obtaining information about individuals contained in the database. Asking highly specific COUNT queries, designed such that the answer will either be 1 or 0, however, enables individual characteristics to be reconstructed. An approach to provide privacy is described by Olken and Rotem [9]: queries are answered against a data sample only, introducing sampling errors and precluding precise computations.

Sampling for Model Validation

To allow **estimation** of the accuracy of a model to be constructed, techniques of data partitioning are widely used. To build a classification tree, for instance, the data are often partitioned into training and test data (holdout method). Sometimes, a third part of the data is necessary to prune the tree. Alternatively, methods like cross-validation or bootstrapping (see **Sampling from Virtual Populations**) are commonly applied [3, 7.9.1].

Sampling for Generating Multiple Models

A way proposed to increase the accuracy of classifiers is that of constructing $k > 1$ models from the same

data first. Given a new data record, each method leads to a certain classification. The class with the most votes (bagging) or the highest-weighted vote (boosting) is then assigned to the new object. Sampling occurs within the construction of the models, where bootstrapping (see **Sampling from Virtual Populations**) is applied: for each $i = 1, \dots, k$, a training set S_i is sampled with replacement, and the i th model is learned from S_i . In the case of boosting, weights are assigned to each training sample and updated during the model-building phase according to previous misclassifications [3, 7.9.2].

Conclusion

A variety of applications of data mining to quality improvement have been reported in literature: data mining to support the development of a metacontroller for the delivery of high-quality aluminum products, data mining to determine the range of control parameters in wafer production, data mining to obtain process parameters minimizing the production of faulty printed-circuit boards, and many more [10]. The above discussion showed that one essential part of data mining in several situations is sampling. The importance of sampling for quality improvement is thus demonstrated for an area outside traditional statistics also.

CHRISTIAN H. WEIB

Sampling in Implementation of Statistical Process Control

Introduction

Quality assurance activities in the manufacturing process consist of proactive activities to build in manufacturing quality at each process step (improve manufacturing process and ensure process capability) and defensive activities to prevent nonconformities from continuing in the production flow. Proactive activities are obviously fundamental to quality assurance. Yet, in spite of proactive activities, nonconformities may eventually occur and have to be prevented from escaping into the process. One means of prevention is 100% inspection; however, this is not to control the process but to determine the acceptability of each unit.

On the other hand, **statistical process control** (SPC) clearly plays a major role in proactive quality assurance activities. Unlike 100% inspection, implementation of SPC is based on sampling to build quality into processes.

The life cycle of SPC (SPC life cycle) to build quality into processes consists of three steps (see, for example, Nishina *et al.* [1]):

1. Ensuring machine performance and then ensuring short-term process capability by pilot production in the preparation stage for mass production.
2. Ensuring long-term process capability in early-stage mass production. Early-stage mass production is the stage when process variation is reduced and the process is brought into the state of statistical control.
3. Maintaining process capability in routine mass production. Routine mass production is the operation and maintenance of process capabilities that were achieved in early-stage mass production.

The above SPC life cycle is a typical approach of parts manufacturing. However, the same approach can be expanded to other fields.

In this chapter, we consider the role of **data collection** by *sampling* in the implementation of SPC over all three life cycle steps. Implementation of SPC obviously varies with the industrial field and the form

of production. Since it is neither possible nor efficient to discuss each of these in detail, attention is restricted to discrete parts manufacturing and semiconductor manufacturing. However, discussion will be held as general as possible. We also provide examples that illustrate problems in applying the concept of inherent process variation, and how to deal with them in general since the inherent process variation can be due to the way items are sampled.

SPC Life Cycle and Sampling

Process Control in Preparation for Mass Production and Sampling

The SPC life cycle starts with ensuring machine performance. Before a production line is formed, it is necessary to confirm that the capability of the individual machines can fully satisfy the product specifications.

An important point here is that, with regard to production process factors, variation is assessed by projecting the situation after the line is formed. It is recommended that an experiment be designed with the factors being the parameters of the assumed production process after the line has been formed, and that variation be assessed from the results (Kuzuya, K., private communication, 2006) – for example, an experimental design in which material conditions are intentionally changed, and variation factors such as conditions before and after exchange of cutting tools, abrasive wheel dressing, or electrodes are incorporated. These experimental factors correspond to noise factors in the Taguchi method. Robustness can be evaluated at the same time in this experiment. At this stage, sampling means collecting data according to the rules of the experimental design, for example, the **orthogonal arrays**.

Implementing the experimental design after a line has been formed is generally very difficult. Conducting an evaluation with consideration of the downstream processes during the upstream stage of SPC will lead to more efficient SPC.

There is also the approach that, to the extent possible, machine performance should be evaluated separately after eliminating the influence of other factors in the production process (for example, ISO DIS 13700 [2]). This method allows evaluation of the contribution of that part of the process variation

2 Sampling in Implementation of Statistical Process Control

caused by machines. However, even if, for example, a large amount of data is obtained under fixed machine conditions using a uniform test piece, the downstream reproducibility of that evaluation is poor. Therefore, the perspectives of achieving good process capability by the ISO approach are not satisfactory.

In the experimental mass production preparation stage, variation is evaluated at the level of individual machines separately. Hence the total process variation of the projected production line is underestimated. One strategy to deal with this effect is to modify the capability calculations. In Japanese industry often the specification range ($S_U - S_L$) is not divided by six times the standard deviation s , but rather

$$P_m = \frac{S_U - S_L}{8s} \quad (1)$$

is used as a machine performance index.

After confirming that the performance of each machine is at a satisfactory level, the production line is formed and the process moves on to pilot production stage. The aim in the pilot production stage is to evaluate and ensure short-term process capability. Since this is a process capability study in short term, the amount of data (about 100 items) is roughly equivalent to a few lots.

The short-term process capability is evaluated from this sample. Whether or not to move to mass production is determined by the short-term process capability evaluation. However, the capability includes little variation due to material and man; therefore, it should be noted that the total process variation of the projected production line is underestimated, e.g., with respect to machine performance.

Process Control in the Mass Production Stage and Sampling

Monitoring and control by Shewhart **control charts** are effective from early-stage mass production through routine mass production. Shewhart control charts can be used for two purposes: (a) to bring a process to a state of statistical control; (b) to judge whether the state of statistical control is maintained. The former role corresponds to the early-stage mass production, and the latter role to the routine mass production.

In either case, Shewhart control charts are set up on the basis of an assessment of the variation

due to chance causes and then they are used to detect the occurrence of assignable causes. Therefore, the identification of chance cause is essential in the development phase of a control chart. Chance causes are related to the inherent variation exhibited by the so-called “5M1E”: Machine, Man, Material, Method, Measurement, and Environment, which are uncontrollable from the technical, economic, and organizational viewpoints.

Shewhart proposed a suitable way to determine the amount of variation due to chance causes. The method is based on relatively small subgroup populations, in which the 5M1E conditions are more or less equal, and the variation due to chance causes from variation within the subgroup is assessed.

Rational subgroups are defined as subgroups *within* which variation is due only to random causes, and *between* which variation is due to special causes. They are selected to enable the detection of any special (assignable) cause of variation among subgroups (by ISO 3534-2 [3]). Ideally such a subgroup is a sample in which all of the items are produced under conditions in which only random effects are responsible for the observed variation (see Nelson [4]). However, in practice it is difficult to specify rational subgroup populations. Generally, subgroup populations are made up in terms of a given day, operator shift or treatment lot, or the like. The essential issue is that rational subgroup populations are made up in terms of a time period, which is related to a physical characteristic as mentioned above.

Subgroup composition and sampling are explained by $\bar{X} - R$ control charts because $\bar{X} - R$ control charts are widely used in comparison with $\bar{X} - s$ and $\bar{X} - s^2$ control chart. Sampling is conducted so that within subgroup variation can be efficiently estimated by the range statistic R . Figure 1 shows an example of sampling in an $\bar{X} - R$ control chart assuming a continuous production process. The example in Figure 1 considers 1 day to be a subgroup population, from which the sample (subgroup) is taken, and the subgroup size to be 4. In $\bar{X} - R$ control charts subgroup size (n) of 4–5 is often used. When, for example, measurement is accompanied by destruction, cases requiring man hours or cost are taken to be $n = 1$. The sampling interval is generally of fixed length (for example, every 2 h) as shown in Figure 1. This is the most practical sampling method based on standardized control methods. Batch sampling should

Figure 1 Sampling with $\bar{X} - R$ control charts (example of continuous production process)

be avoided as it underestimates the size of within subgroup variation and produces **bias** in the estimate of process mean.

Other sampling strategies with varying sampling intervals or varying sample sizes have been proposed (see, for example, Reynolds *et al.* [5] and Park *et al.* [6]); however, these approaches have not been yet utilized. They may be applied to monitoring the condition-based maintenance of equipment.

Manufacturing standards are improved in early-stage mass production, and when a sufficiently high process capability is obtained and a state of statistical control is achieved, the process proceeds to routine mass production. At this time, the process capability and the **process capability index** C_p are calculated as

$$\text{Process capability} = 6 \times \frac{\bar{R}}{d_2} \quad (2)$$

$$C_p = \frac{S_U - S_L}{6 \times \bar{R}d_2} \quad (3)$$

from within subgroup variation. Here, $\bar{R}$ is the value of the center line in the R control chart, and d_2 is a coefficient for the unbiased **estimation** of the standard deviation from the range R . In other words, the within subgroup variation on the $\bar{X} - R$ control chart is considered as the inherent process variation, and in routine mass production process, variation is controlled so that it is maintained as the inherent process variation.

In practice, however, Caulcutt [7] and Kuzuya [8] pointed out that the within subgroup variation is not necessarily the inherent process variation. Kuzuya [8] investigated 63 cases of control charts in the stage of routine mass production used for monitoring essential quality characteristics for processes exhibiting a capability index exceeding 1.33. He found that half of the X or $\bar{X}$ charts triggered alarms, thus confirming Caulcutt's results [7]. Nishina *et al.* [1] proposed a measure in which the variation due to chance causes includes some of the variation between subgroups and showed a case study of the measure. It is essential that the process capability in early-stage mass production

is regarded as the standard value of variation due to chance causes in routine mass production. Especially, in batch processing there may be cases where it is not appropriate to view variation from within-batch sampling as variation due to a chance cause.

Sampling to Prevent the Escape of Nonconforming Product

In routine mass production, quality checks by sampling are done to prevent the escape of nonconforming product. At such instances, the quality check is generally determined with the use of a go–no-go gage.

A shift in the 5M1E of production is always followed by a “first item check”. There is a shift in the 5M1E when, for example, a changeover of operator shift is made, a changeover in the material lot is made, or immediately after maintenance.

In addition to the first item check, regular quality checks, in which generally one item is sampled, are conducted at given time intervals. The sampling interval of the regular quality checks is determined with consideration of traceability when a quality problem is discovered (in a parts plant, for example, the time up until the parts are shipped in the truck yard). Some plants use acoustic signals to indicate regular quality checks at periodic intervals, e.g., at 2-h intervals. In machining processes, there are also cases when quality checks are done after a fixed number of pieces, based on the consideration of cutting tool life.

Conditions for this quality check system are (a) the development of a flow production system infrastructure guaranteeing traceability of products; (b) being in routine mass production, in which process capability is high (for example, process capability index $C_p \geq 1.33$); and (c) that the process is in a state of statistical control. This means that, if there are no quality problems in a successive regular quality check, all products in the check interval are assured to be in conformity; in additions, in the event that a nonconforming item is discovered, one allows to trace all products corresponding to the immediately

4 Sampling in Implementation of Statistical Process Control

preceding regular quality check interval. However, it should be kept in mind that sampling to prevent escape of nonconformities into the production flow is not a control activity to lead directly to process improvement.

Practical Cases with Respect to Inherent Process Variation and Sampling

Sampling is closely related to the formation of inherent process variation. This section shows two examples that illustrate how inherent process variation is formed.

Inherent Process Variation in Attribute Control Charts and Sampling

A description of inherent process variation and sampling error will be given for c control charts, considering a semiconductor manufacturing process. In semiconductor manufacturing, particles need to be controlled with respect to various factors. The quality characteristic to be controlled is the number of particles on a single wafer taken from a processed batch. The sampling method is illustrated by Figure 2. In this case, the wafers are considered as items and the batches are subgroup populations. One wafer in a batch is taken as sample since it is known that the variation between the wafers in a batch is relatively small.

SPC literature shows that c control charts are applied to this case. The control limit of the c control chart is

$$\bar{c} \pm 3\sqrt{\bar{c}}$$

Here, $\bar{c}$ is the mean value for the number of particles. c control charts are established on the assumption that the quality characteristic follows a Poisson distribution. This assumption deserves some caution: it is valid only under the condition that the probability of particle attachment is uniform on the wafer and that the number of positions on the

wafer that potentially carry a particle is large. Under these assumptions, for the sampling method shown in Figure 2, only the sampling error is considered as the inherent process variation on c control charts with $\bar{c} \pm 3\sqrt{\bar{c}}$ control limits. That is, the elements in the 5M1E factors of the production process are not included in the inherent process variation.

However, the inherent process variation may include variation due to sources other than the sampling error in the case of the sampling shown in Figure 2. Figure 3 shows a c control chart for particle control in a process in the semiconductor wafer process. Judging from the usually observed data, it is difficult to say that the data in Figure 3 indicate an abnormal state. However, many points are beyond the control limits, and this is not a suitable basis for control charting. The behavior in Figure 3 should be considered as variation due to chance cause, and shows that the variation on the wafer is not sampling error only. The particle attachment rate may be not uniform on the wafer, and the variation due to chance cause needs to be obtained with consideration of the variation in the particle attachment rate on the wafer. One measure that has been proposed for this situation is to assume a negative binomial distribution rather than a Poisson distribution for the particle number distribution [9]. Figure 4 shows a control chart using control limits that assume a negative binomial distribution. The control chart in Figure 4 shows a state of statistical control, and illustrates that it is valid to assume a negative binomial distribution for the particle number.

This example illustrates the relation between sampling error in count data and inherent process variation.

Inherent Process Variation Related to Pattern on Two Dimensions

This section explains the inherent process variation related to patterns in the chemical mechanical polishing (CMP) process, a semiconductor wafer process. The CMP process is a process to polish and plane

Figure 2 Sampling with an attribute control chart

Figure 3 P article number control chart (conventional c control chart)

Figure 4 Control chart assuming a negative binomial distribution for particle number

wafer surfaces, excluding irregularities in the film that forms the wafer surface. The quality characteristic of this process is the thickness of the film that remains after polishing.

In the CMP process, one lot consists of 25 wafers. Polishing is done for each wafer unit, but the process parameters are not changed within a lot. Process variation can be broken down into variation between lots, variation within a lot, and variation on a wafer. This process has the following characteristics.

1. Variation on a single wafer is large, and has a pattern.
2. Variation within a lot is small.
3. Variation between lots is large (shows a trend according to abrasive wheel friction).

In this process, therefore, between-lot trends and within-wafer variation must be controlled.

The remaining film in this process is measured on the nine points on the wafer shown in Figure 5.

Figure 5 Measurement points of remaining film thickness in a wafer (numerals stand for measurement points)

The between-lot variation and within-wafer variation are controlled using the data from these nine points. Since the within-lot variation is small, it is sufficient to sample one wafer in a lot.

The amount of polishing is adjusted by the polishing time. Between-lot variation can be handled by feedback control as the modulator for polishing time. Automatic process control is often used as shown for this handling in the semiconductor process.

In processes such as the semiconductor production process, equipment maintenance is a key control activity in routine mass production. Since maintenance costs are high, the maintenance period is extended as long as possible. Higashide *et al.* [10] proposed statistics to indicate the maintenance period from data measured on the nine points in Figure 5.

In the target process, there is an inherent process pattern in the within-wafer variation, and there was a change in that pattern before and after maintenance. Higashide *et al.* used principal component analysis for the matrix of the sum

of products following a double centralized transformation, $y_{i \times j}$, shown in equation (4) to identify inherent process pattern in the within-wafer variation.

$$y_{i \times j} = y_{ij} - \bar{y}_{i \cdot} - \bar{y}_{\cdot j} + \bar{\bar{y}} \quad (4)$$

Here, y_{ij} is the remaining film thickness at position j on the i th wafer. $\bar{y}_{i \cdot}$ and $\bar{y}_{\cdot j}$ indicate the row and column averages of the data matrix (sample $\times$ measurement position), respectively, and $\bar{\bar{y}}$ stands for the total average of the data matrix.

As a result of principal component analysis, the contribution rate of the first principal component is about 50%, and the first principal component score may be considered to show the majority of the remaining film thickness pattern. The first principal component score is shown in a **time series** in Figure 6. From Figure 6, the first principal component score shows a downward trend before maintenance. After maintenance a big swing in the positive direction is observed. If a weighting factor to calculate the first principal component score is determined from the early-stage mass production data, the timing of the maintenance period in routine mass production and the maintenance effect can be monitored.

Conclusion

The SPC life cycle consists of the stages of mass production preparation, early-stage mass production, and routine mass production. The article gives a practical description of the kind of data that should be obtained by sampling for the objective of reducing process variation at each cycle step.

Fundamentally, in the mass production preparation stage, data should be acquired using experimental design methods. In early-stage mass production, data

Figure 6 Time series of first principal component scores (the dotted lines stand for maintenance time)

should be acquired through on-line monitoring that will help to achieve process improvements and a state of statistical control. In routine mass production, data obtained should be such that it will help in operation and maintenance of processes such as equipment maintenance, using a standardized monitoring method. In addition, sampling is needed for quality checks to prevent the escape of nonconforming products in the mass production stage.

Sampling is closely related to the assessment of inherent process variation. It is essential to grasp what is considered as inherent process variation.

Sampling from Virtual Populations

Introduction

As the complexity of problems and methods for performing statistical inference in quality and reliability increases, the availability of simple solutions becomes rare. For example, the computation of the **average run length** for a **control chart** may be simple when the process is normally distributed. However, the average run length under other distributions, or when the process distribution is unknown, may be difficult, if not impossible, to compute in a closed form. In such cases simulation methods such as the **bootstrap** can be used to estimate the average run length of the control chart. Another example occurs when using process-capability indices to evaluate the capability of a process. Even when the process distribution is normal, many of the standard process capability indices in use today do not have simple closed-form procedures for computing **confidence intervals** or performing hypothesis tests. Asymptotic approximations have been developed for many of the problems discussed above. However, these approximations may not provide the accuracy required for industrial use. In such cases methods based on computer simulations and the bootstrap can often be used to obtain approximate confidence intervals and tests.

Let $\mathcal{X} = \{X_1, \dots, X_n\}$ be a set of independent and identically distributed random variables from a distribution $F \in \mathcal{F}$, where $\mathcal{F}$ is a collection of distribution functions (see **Cumulative Distribution Function (CDF)**). This relationship will be denoted as $\mathcal{X} \sim F$. Let θ be a functional parameter of F . That is, $\theta = T(F)$ for some $T : \mathcal{F} \rightarrow \mathbb{R}$. Let $\hat{\theta}$ be an estimator of θ (see **Estimation**). Of interest is performing statistical inference to learn about the true value of θ based on the sample $\mathcal{X}$. Such methods generally require the sampling distribution of $\hat{\theta}$ or of a related function $R_n(\theta, \mathcal{X})$. Often the function $R_n(\theta, \mathcal{X})$ is a test statistic for hypothesis testing or a pivotal quantity for generating confidence regions (see **Confidence Intervals; Hypothesis Testing**). Define $H_n(R, t) = P[R_n(\theta, \mathcal{X}) \leq t | \mathcal{X} \sim F]$ as the sampling distribution of interest. Let $h_\xi = H_n^{-1}(R, \xi) = \inf\{t : H_n(R, t) \geq$

$\xi\}$ be the ξ th quantile of $H_n(R, t)$ for any $\xi \in (0; 1)$ (see **Quantiles**).

As an example, suppose $\mathcal{X} \sim F \in \mathcal{F}$, where $\mathcal{F}$ is the collection of all normal distributions with mean θ and variance $\sigma^2 < \infty$ (see **Normal Distribution**). Let $R_n(\theta, \mathcal{X}) = n^{1/2}(\hat{\theta} - \theta)/\hat{\sigma}$ where $\hat{\theta}$ and $\hat{\sigma}$ are the usual sample mean and standard deviation computed on the sample $\mathcal{X}$. The $R_n(\theta_0, \mathcal{X})$ is the well-known t statistic for testing the null hypothesis $H_0 : \theta = \theta_0$. This particular choice of $R_n(\theta, \mathcal{X})$ can also be used to derive a confidence interval for θ .

There are several basic situations that can occur in statistical inference:

1. If F is known then $H_n(R, t)$ and h_ξ will be known, though they may not have a closed form. When $H_n(R, t)$ does not have a closed form, empirical methods based on simulations can be used to approximate $H_n(R, t)$ to any specified degree of accuracy.
2. If F is unknown, the structure of $R_n(\theta, \mathcal{X})$ and $\mathcal{F}$ may allow the form of $H_n(R, t)$ to be known, or be approximated using simulation.
3. If F and $H_n(R, t)$ are both unknown, then $H_n(R, t)$ must be estimated, usually using the bootstrap.

This article will address the issue of the sampling mechanism used for each of these cases when simulation must be used to approximate, and perhaps estimate, the sampling distribution $H_n(R, t)$. In each of these cases samples are generated from a *virtual population*, one which is used as a proxy for the actual population from which the original data were sampled. This article will also address the issue of sampling from virtual populations that do not fit within the framework of independent and identically distributed sampling developed above, specifically regression and **time series** applications.

Virtual Populations

In each case studied in this section the virtual population used with the sampling mechanism in simulations is chosen so that the virtual population and sampling mechanism mimic the true population and sampling mechanism as close as possible. Several cases are studied below.

2 Sampling from Virtual Populations

F Known

Consider the case where F is completely known but $H_n(R, t)$, and hence h_ξ does not have a closed form. In this case the distribution $H_n(R, t)$ can be approximated empirically as follows.

1. Generate b samples of size n from F . That is, sample $\mathcal{X}_i^* \sim F$ for $i = 1, \dots, b$. Each sample, and the components of the sample should be mutually independent.
2. Calculate $R_i^* = R_n(\theta, \mathcal{X}_i^*)$ for $i = 1, \dots, b$.
3. Approximate the distribution function $H_n(R, t)$ with the empirical distribution function computed on $R_1^*, \dots, R_b^*$,

$$H_n(R, t) \simeq \tilde{H}_n(R, t) = b^{-1} \sum_{i=1}^b \Omega(R_i^* \leq t) \quad (1)$$

where $\Omega(B)$ is the indicator function of a set B .

This method of approximating $H_n(R, t)$ is not new. Gossett implemented this method in his investigations of what became the t distribution. These results were published in 1908 [1].

To generate the samples required in step 1, usually uniform (pseudo) random numbers are generated on a computer, using a random number table, or by some other electronic or physical device. Observations following the distribution F are then generated by transforming the uniform observations through F^{-1} . Other methods, such as acceptance–rejection methods, can be used as well. For example in [1] the device used to generate the samples was a well-shuffled deck of cards which had the values in the population written on them. Many software packages, such as The R Computing Environment which is freely available for most platforms at www.r-project.org, also offer convenient methods for generating random observations from most of the common statistical distributions. An overview of these methods can be found in [2].

The empirical distribution function used in step 3 provides a convenient nonparametric method for approximating $H_n(R, t)$ based on the simulated samples. With respect to the sampling frame within the simulation when n and F are fixed, $\tilde{H}_n(R, t)$ is pointwise unbiased and pointwise consistent as $b \rightarrow \infty$, and has the property

$$\lim_{b \rightarrow \infty} \sup_{t \in \mathbb{R}} |\tilde{H}_n(R, t) - H_n(R, t)| = 0 \quad (2)$$

which is implied by the Glivenko–Cantelli theorem [3]. This property implies that the approximation $\tilde{H}_n(R, t)$ can be made arbitrarily accurate by taking b to be large enough. The choice of b is crucial to the accuracy of the approximation. No simple rules exist for choosing b due to the variety of problems that can be solved by this method. For example, if the tails of $H_n(R, t)$ are of interest then larger values of b would be required compared to the case where the mean of $H_n(R, t)$ is of interest. An overview of some basic methods for determining how long a simulation should run can be found in [4].

The percentile h_ξ can be approximated as

$$h_\xi \simeq \tilde{h}_\xi = \inf_{t \in \mathbb{R}} \{t : \tilde{H}_n(R, t) \geq \xi\} = R_{(i)}^* \quad (3)$$

when $i/b < \xi \leq (i+1)/b$ for $i = 1, \dots, b-1$, where $R_{(i)}^*$ denotes the i th largest value in $R_1^*, \dots, R_b^*$. Other versions of the sample quantile computed on $R_1^*, \dots, R_b^*$ can be used as well.

F Unknown, R Distribution Free

When F is unknown it is helpful to determine whether $R_n(\theta, \mathcal{X})$ is *distribution free* over the collection $\mathcal{F}$, which implies that $R_n(\theta, \mathcal{X})$ has the same distribution regardless of which $F \in \mathcal{F}$ in the parent population. In this case the algorithm described above can be implemented without any changes where F can be taken to be *any* member of $\mathcal{F}$.

Returning to the earlier example, suppose $\mathcal{X} \sim F \in \mathcal{F}$, where $\mathcal{F}$ is the collection of all normal distributions and let $R_n(\theta, \mathcal{X}) = n^{1/2}(\hat{\theta} - \theta)/\hat{\sigma}$. It is well known that $R_n(\theta, \mathcal{X})$ follows a t distribution with $n-1$ **degrees of freedom**, regardless of which member of $\mathcal{F}$ the population follows (see **Probability Density Functions**). This implies that $R_n(\theta, \mathcal{X})$ is distribution free on the collection of normal distributions. This means that if the form of the t distribution were unknown, but it is still known that $R_n(\theta, \mathcal{X})$ is distribution free, one could simulate samples from *any normal distribution* to approximate the form of the t distribution.

F Unknown, R Not Distribution Free

The case of broadest application occurs when F is an unknown member of $\mathcal{F}$ and either it is not known whether $R_n(\theta, \mathcal{X})$ is distribution free over $\mathcal{F}$, or it is known that $R_n(\theta, \mathcal{X})$ is not distribution free over

$\mathcal{F}$. In this case, it is not possible to find $H_n(R, t)$ exactly, but it can be estimated using the *bootstrap* developed by [5]. The bootstrap estimate of $H_n(R, t)$ is computed by finding the distribution of $R_n(\theta, \mathcal{X})$ under the assumption that the population F is really equal to an estimate of F , conditional of the observed sample $\mathcal{X}$. That is, the bootstrap estimate of $H_n(R, t)$ is given by Efron

$$\hat{H}_n(R, t) = P^*[R_n(\hat{\theta}, \mathcal{X}^*) \leq t | \mathcal{X}^* \sim \hat{F}] \quad (4)$$

where $P^*(A)$ represents the conditional probability measure $P(A|\mathcal{X})$ and $\hat{F}$ is an estimate of F . Note that the calculation of the bootstrap estimate in equation (4) does not necessarily imply the need for a simulation to carry out the required calculations. In fact [5] presents an example based on the binomial distribution where the bootstrap estimate in equation (4) can be computed explicitly. For other examples where functions of $\hat{H}_n(R, t)$ can be computed explicitly, see [6, 7]. In other cases, analytic approximations such as the saddle point approximation and the delta method can also be used. See [5], [8–11] for examples of these types of applications. The normal approximation $H_n(R, t) \simeq \Phi(t)$ is another type of approximation usually applicable when the central limit theorem applies to the statistic $H_n(R, t)$. However, in many cases a simulation approximation such as the one described above is implemented to approximate the bootstrap estimate as it rarely exists in closed form and either many of the approximations require complex computations or the approximations are not accurate enough for the problem being studied. The only change required in the algorithm described above is that the sampling in step 1 should be from $\hat{F}$, conditional on $\mathcal{X}$, instead of F itself.

The most common estimator used for F is the empirical distribution function defined in equation (1) computed on $\mathcal{X}$. Note that conditional on $\mathcal{X}$, the empirical distribution function computed on $\mathcal{X}$ corresponds to a discrete mass function that places a mass of n^{-1} on each of the observed sample points in $\mathcal{X}$. Therefore, generating samples from the empirical distribution function of $\mathcal{X}$ is equivalent to sampling n times, with replacement, from the observations in the original sample $\mathcal{X}$. This type of sampling is usually called **resampling**. The key to the success of the application of the bootstrap in many problems is that under specific conditions on F and $R_n(\theta, \mathcal{X})$ the

bootstrap provides a consistent estimate of $H_n(R, t)$. For a summary of the major results see Chapter 3 of [12]. In addition, when the parameter of interest θ is a smooth function of a mean vector, it can be shown that the bootstrap provides an asymptotically more accurate estimate of $H_n(R, t)$ than is given by the central limit theorem.

More efficient methods, that is methods that require smaller values of b to obtain the same accuracy, for performing resampling have been developed using algorithms from the statistical computing literature. Examples of these algorithms include balanced resampling [13], centering [14], and antithetic resampling [15].

In some cases the use of the discrete empirical distribution as the estimator of F , and hence the virtual sampling population, becomes problematic. This is particularly true when the parameter θ is not a smooth function of F , for example when θ is a percentile of F such as the median. See [16] and [17]. The usual alternative estimate used for F in this case is a smoothed estimate such as a kernel distribution function estimate, or equivalently, a kernel density estimate. See [18] for a detailed theory of these estimates. Other methods for computing smooth estimates of F have also been developed (see **Density and Failure Rate Estimation**). See [19] and [20] for an exposition of some of these estimates.

Virtual Error Populations

Sampling from virtual populations is also used for data that are not independent and identically distributed. Consider the standard general linear model where an n -dimensional random vector $\mathbf{Y}$ is observed conditional on an observed and fixed $n \times p$ matrix $\mathbf{X}$ with the property that $E(\mathbf{Y}|\mathbf{X}) = \mathbf{X}\boldsymbol{\theta}$ where $\boldsymbol{\theta}$ is a p -dimensional vector of unknown constants. The usual model used to generate this type of data is of the form $\mathbf{Y} = \mathbf{X}\boldsymbol{\theta} + \boldsymbol{\epsilon}$ where $\boldsymbol{\epsilon}$ is an n -dimensional random error vector with mean vector $E(\boldsymbol{\epsilon}) = \mathbf{0}$ and **covariance** matrix $V(\boldsymbol{\epsilon}) = \sigma^2\mathbf{I}$, where $\mathbf{0}$ is an n -dimensional vector whose entries are all 0 and $\mathbf{I}$ is the identity matrix. It is usually assumed in this case that the components of $\boldsymbol{\epsilon}$ are mutually independent. Using this structure, it will be assumed that the components of the error vector can be represented as a set of independent and identically distributed random variables from a distribution F , called the *error distribution*.

Note that while the components of the error vector are independent and identically distributed, the components of $\mathbf{Y}$ are not identically distributed except in special cases. Many common statistical techniques fall within the framework of the linear model. These include linear regression analysis and analysis of variance techniques.

The parameter vector θ is usually estimated by minimizing $\|\mathbf{Y} - \mathbf{X}\theta\|_q$ where $\|\mathbf{w}\|_q$ is the L_q norm. Let $\hat{\theta}$ be an estimator of θ , $R_n(\theta, \mathbf{X}, \mathbf{Y})$ be a function of θ , $\mathbf{X}$, and $\mathbf{Y}$, and $H_n(R, t) = P[R_n(\theta, \mathbf{X}, \mathbf{Y}) \leq t | \epsilon_1, \dots, \epsilon_n \sim F]$. Inequalities between vectors will be interpreted elementwise. When $\mathbf{X}$ is full rank then the estimator exists uniquely and the model is usually called a *regression model*. When $\mathbf{X}$ is not full rank then $\hat{\theta}$ is not unique and only estimable functions of θ can be uniquely estimated. It will be assumed that if $R_n(\theta, \mathbf{X}, \mathbf{Y})$ is a function of $\hat{\theta}$ in this case, then it is an estimable function.

As an example consider the case of linear regression fitted by **least squares** ($q = 2$). Assuming that $\mathbf{X}$ has full rank and that F is normal, it follows that the function

$$R_n(\theta, \mathbf{X}, \mathbf{Y}) = \frac{(n-p)^{1/2} \mathbf{e}_j' [(\mathbf{X}'\mathbf{X})^{-1} \mathbf{X}'\mathbf{Y} - \theta]}{[(\mathbf{Y}'\mathbf{Y} - \hat{\theta}'\mathbf{X}'\mathbf{Y}) \mathbf{e}_j' (\mathbf{X}'\mathbf{X})^{-1} \mathbf{e}_j]^{1/2}} \quad (5)$$

follows a t distribution with $n-p$ degrees of freedom where $\mathbf{e}_j$ is a vector whose j th element is equal to 1 and the remaining elements are equal to 0. This function can be used to derive confidence intervals and tests for the j th element of θ .

In the case of least-squares fitting ($q = 2$) with a normal error distribution, there are many analytical results about the distribution of useful functions $R_n(\theta, \mathbf{X}, \mathbf{Y})$ (see **Least-Squares Estimation**). When the error distribution is not normal or it is unknown, or the least-squares criteria are not used for estimating θ , fewer analytical results are known and simulation methods and approximations become more important. The most common approximation in this case is given by the central limit theorem for regression models [21]. When analytic results are not available and approximations are either not available or not practical, the simulation method presented in the previous section can be adapted to these types of models as well.

To perform simulations for regression models, new $\mathbf{Y}$ vectors need to be generated conditional on $\mathbf{X}$ when

θ is unknown. The most common solution to this problem begins by obtaining the estimate $\hat{\theta}$ from $\mathbf{X}$ and $\mathbf{Y}$. If F is known, or $R_n(\theta, \mathbf{X}, \mathbf{Y})$ is distribution free over $\mathcal{F}$ and $F \in \mathcal{F}$, then new $\mathbf{Y}$ vectors can be generated by first simulating a sample of size n from the error distribution F . Call this generated vector $\mathbf{r}^*$. The new $\mathbf{Y}$ vector is then generated as $\mathbf{Y}^* = \mathbf{X}\hat{\theta} + \mathbf{r}^*$. This process is repeated b times and $R_n(\theta, \mathbf{X}, \mathbf{Y}^*)$ is computed for each generated $\mathbf{Y}^*$ vector. The distribution of $R_n(\theta, \mathbf{X}, \mathbf{Y}^*)$ can then be approximated with the empirical distribution of the b simulated values of $R_n(\theta, \mathbf{X}, \mathbf{Y}^*)$.

If F is unknown and there is no distribution-free result, the residual vector $\mathbf{r}$ is computed as $\mathbf{r} = \mathbf{Y} - \mathbf{X}\hat{\theta}$ (see **Residuals**). The vector $\mathbf{r}^*$ is then generated by resampling from $\mathbf{r}$, or equivalently sampling from the empirical distribution of the elements of the residual vector. These methods have been studied theoretically and empirically by [16, 22–26].

It has been noted that the **residuals** are not independent of one another while the components of the error vector are. To account for this fact, Efron [27] suggests transforming the residuals before resampling. Another approach is to use external bootstrap resampling. The external bootstrap resamples from a continuous distribution with certain characteristics. See [26] and [28]. When $\mathbf{X}$ is stochastic, the paired resampling algorithm has also been suggested. See Chapter 7 of [12].

The sampling distributions of functions of parameter estimates from time series models can also be approximated using similar methods to those used in linear models (see **Time Series Analysis**). Methods based on resampling residuals from fitted time series models have been proposed. See Chapter 9 of [12] and [29–31] for further details and alternative methods.

Internal and External Quality Measures

Use of Surveys to Improve Quality

There are two distinct general approaches to the use of statistical methods in quality improvement. These are the *production approach* and the *marketing approach*.

The *production approach* focuses on quality improvement from the management (internal) viewpoint. Quality standards in this framework can be expressed either in nonmonetary or monetary terms and applied in observation as well as inferential studies. The observations studies build on the application of the basic statistical **quality control** toolbox, which includes check sheets, **Pareto** charts, histograms, scatterplots, **control charts**, flowcharts, and other simple tools [1]. The inferential studies build on the application of the design of experiments (**DOE**) with the goal of preventing flaws in products and services due to a poor design [2].

The *marketing approach* focuses on the customer (external) assessment of quality using tools of survey research. Emphasis is on the analysis of quality attributes and analysis of overall quality. Like in the production approach, quality standards in the framework of the marketing approach can be expressed in nonmonetary or monetary terms. When defining quality standards in nonmonetary terms, there is little room to avoid the highly subjective *customer expectations* formed through the following attributes see [3–5]:

- *Search attributes* which are determined and evaluated *before* the product or a service is delivered (e.g., price or design).
- *Experience attributes* which are experienced either *during* or *shortly after* the delivery (e.g., taste or duration of well being).
- *Belief* (or *credence*) *attributes* which may be impossible to evaluate even a *long time after* the delivery (few customers possess technical skills sufficient to evaluate whether the car maintenance procedures were necessary and performed in a proper manner).

Because the customer expectations are unavoidable, companies usually try to *create* such expectations that can and will be met with the actual product or service performance. One way to effectively create expectations is the use of branding (brands function as a quality warranty, signaling reliability and consistency of a product or service).

Apart from customer expectations, *customer intentions* can also be used as subjective nonmonetary quality standards. This is problematic when they reflect the ideal rather than actual buying behavior of customers who act as quality evaluators.

Further differences of the production and marketing approach with respect to the use of statistical methods in quality improvement are summarized in Table 1.

One of the most frequently used standard survey measurement instruments in quality improvement is SERVQUAL (discussed in **SERVQUAL Surveys**).

Integrating Internal and External Quality Measures

The idea to link internal (facilitated by the production approach) and external (facilitated by the marketing approach) quality measures is not a new one. Management problems are often associated with coordinating, evaluating, and using both sets of quality measures to improve decision-making processes [6].

At the general level, the need to integrate the production/operations and marketing approaches, and to address interactions between them with the goal of improving quality has been widely recognized [7, 8]. Kordupleski *et al.* [9] write

“... there must be a link between customer needs and processes that can be directly managed. We should attempt to construct, for each customer need, an internal metric associated as closely as possible with that customer need. If we are successful, there should be a strong statistical relationship between the internal metric and the quality score for the corresponding customer need” (p. 85).

In the service sector, companies have traditionally managed services by manipulating operations attributes and observing market outcomes [10]. The problem is that in their initial efforts to increase customer satisfaction, many companies tend to focus on tracking customer survey ratings over time or

2 Internal and External Quality Measures

Table 1 Comparison of production and marketing approach to quality improvement

Criteria of comparison	Production approach	Marketing approach
Theoretical background	Classical texts on statistical quality control	Texts on service management and marketing
Product bundle	Emphasis on tangible components	Emphasis on intangible components
Predominant focus	Internal (back office – design and production – technical quality)	External (front office – delivery – perceived quality)
Standards	Objective (precisely determinable)	Subjective (customer expectations, customer intentions, and so on)
Statistical toolbox	Traditional SQC toolbox	Survey toolbox
Mode of application	Ex-ante, real time, and ex-post	Rarely in real time, usually ex-post
Goal of application	Design quality into service processes to prevent negative service experiences	Use customer feedback to discover areas in need of quality improvement
Quality of tangible components	Measured directly with an array of different tools	Measured indirectly through expert and customer observations
Quality of intangible components	No tools available	Measured indirectly through expert and customer observations
Resulting measures	Direct process measures	Indirect customer perception measures
Time frame of measurement	Measures available relatively quickly	Measures available with considerable delay
Cost of measurement	Measures obtained at a low cost	Measures obtained at a high cost (due to survey design, implementation, and evaluation)
Frequency of application	Very high (e.g., hourly, daily ...)	Very low (e.g., annually or biannually)
Required level of employee quantitative literacy	Includes some of the simplest methods applicable with a minimum of educational effort	Includes some of the most complex analytical methods – proper training necessary to avoid the danger of simplification through pull-down menus in statistical software packages

benchmarking them against those of competition. In other words, customer survey ratings become a goal in their own right, when they should rather be integrated with internal quality measures. Low customer survey ratings should be understood as clear signals of the necessity to redesign service processes [11] and *vice versa* as it should be possible for companies to predict how changes in design affect customer satisfaction, behavior, and revenues.

Systems for developing and delivering services to the customer have the same inherent possibility for human weakness, error, and failure as the systems used for product development and delivery in the manufacturing sector [12]. Consequently, opportunities for quality improvement in the service

and manufacturing sectors are based on similar premises:

- less-than-satisfactory quality internal to an organization results in higher operating costs;
- less-than-satisfactory quality as delivered to the customer causes a negative impact on revenues.

In other words, manufacturing companies could also greatly benefit from integration of internal and external quality measures.

Simple as such integration might seem in theory it is not easy to implement in practice. A number of problems are encountered exclusively at the level of external quality measures. *Direct external quality measures* such as customer survey ratings

are available with considerable delay. Fortunately, there also exist *indirect external quality measures*, which are available on a continuous basis given that certain prerequisites are fulfilled. *Purchase volume* and *purchase frequency* are two such measures which tend to be closely linked to customer survey ratings.

To explore the nature of relationships between internal and external quality measures, data collected in different types of company/customer contacts (e.g., at the point of sale, through personal or telephone complaints, thank you letters, customer surveys, and so on) should be available simultaneously. Preferably, they should also be linked together by means of a unique customer identifier.

There are not that many cases where companies could get hold of these data simultaneously. Although technical requirements to uniquely identify customers, and to collect, store, and analyze their purchase data, have already been fulfilled, some kind of a formal relationship has to exist between a company and its customers.

Creation of formal relationships to facilitate customer **data collection** seems the easiest in the framework of a loyalty program, although other possibilities also exist. An additional prerequisite for attempts at integrating internal and external quality measures is the company's ability to roam the data warehouse harboring internal and external data, and face the challenge of building adequate integrative models.

Sampling Designs in Surveys

Introduction

Surveys are very popular. They help to detect structures in a population and their results inform decision making. In market research, a typical question is whether a new product will find a market. In empirical social sciences surveys investigate attitudes, beliefs, and behavior patterns of groups of peoples. Opinion polls are surveys of opinion often in connection with election studies. Surveys carried out by national statistical offices yield important statistics that are then officially published, e.g. the number of unemployed. Most surveys have one thing in common: only a small number of people are asked a series of questions, and their answers are then extrapolated to a larger group. There are very different ways to select respondents for a survey. If statistical inferences or generalizations from the selected persons are planned, sampling designs based on **probability theory** are adequate techniques. For a small selection of recommended books on sampling see [1–6].

Populations

Before starting a survey, an investigator should exactly define which *population* he or she wants to study and what the objective of the survey is, i.e., what information on *population characteristics* should be collected, e.g., the percentage of patients satisfied with a hospital service, the total expenses of a class of customers for a type of product, or the value of articles in an inventory. This is often not an easy task since the definition of this *target population* needs to specify regional, temporal, and substantive aspects. Usually a population of N distinct units (patients, customers, articles) can be identified with the set $U = \{1, \dots, N\}$. Each unit i bears a characteristic value y_i , e.g., a satisfaction indicator with $y_i = 1$ for “satisfaction”, $y_i = 0$ for “dissatisfaction”, the expenses y_i of customer i , the value y_i of article i . Most often, as in the above examples, the interesting population characteristic is the population total $Y = \sum_{i=1}^N y_i$, or, equivalently, the population mean $\bar{Y} = Y/N$. If it is possible to compile a list of all elements of the target population then this is an excellent

starting point for implementing random sampling. Employee attitude surveys are good examples of surveys that can use easily available lists. Sometimes, such lists do not exist and the researcher has to look for an adequate *frame* to obtain access to the elements of interest. In a telephone survey, telephone books are the basis for sample selection and form the so-called sampling frame. The telephone numbers are the sampling units of the sampling frame. Obviously, two *errors of coverage* can appear. First, *overcoverage*, i.e. there are elements in the sample, which do not belong to the target population, such as business telephone numbers in a survey of private households only. Second, people without telephone are not included and therefore have a zero chance of being selected. This is called *undercoverage*. When planning a survey, it is important to carefully consider the amount of overcoverage and undercoverage and its influence on the data and the interpretation of results.

Sampling

A *sample* s of size n from a population $U = \{1, \dots, N\}$ is a sequence $s = (i_1, \dots, i_n)$ of elements $i_1, \dots, i_n$ selected from U . The order $i_1, \dots, i_n$ of the sample components reflects the order of appearance, if the sample results from a draw-by-draw mechanism. Under *sampling with replacement*, repetitions can occur among the components $i_1, \dots, i_n$, whereas under *sampling without replacement* the components are distinct from each other. Associated with the sample elements $i_1, \dots, i_n$ are the *data* d defined by the sequence of pairs $d = \{(i_1, y_{i_1}), \dots, (i_n, y_{i_n})\}$, shortly $d = \{(i, y_i) : i \in s\}$ where $i \in s$ indicates the enumeration of the components of the sample s .

We distinguish between *random samples* and *non-random samples*. A simple example for a nonrandom sample is a television show that holds a vote on the best song on their show – obviously, only people watching the show can actually form a part of the sample. Other examples are quota samples or convenience samples. *Random samples*, as considered in the sequel, result from a nondeterministic selection mechanism, which is characterized by the selection probabilities $p(s)$ for the possible sample s . The probabilities $p(s)$ determine the *sampling design*. Under *simple random sampling (SRS)* all samples have the same probability of being selected. Hence, in case of SRS without replacement $p(s) = 1/\binom{N}{n}n!$ for all s

2 Sampling Designs in Surveys

and in case of SRS with replacement, $p(s) = 1/N^n$ for all s . Given a design $p(s)$, $\pi_i, i = 1, \dots, N$, denotes the *inclusion probability* of unit i in the sample. In the SRS case $\pi_i = n/N$ for $i = 1, \dots, N$. The second-order inclusion probability of selecting unit i and j in the sample is denoted by π_{ij} and $\pi_{ii} = \pi_i$. For $i \neq j$ in SRS without replacement, $\pi_{ij} = n(n-1)/N(N-1)$ in contrast to SRS with replacement, where $\pi_{ij} = \pi_i \pi_j = n^2/N^2$.

National statistical offices often use *systematic sampling* in their surveys. In its simplest form, systematic sampling can be described as follows, assuming for simplicity that $N = n \cdot H$, where H is the sampling interval: randomly draw a number K ($1 \leq K \leq H$) and select the elements $K, K+H, \dots, K+(n-1)H$. In Figure 1 this selection process is illustrated for $n = 6$.

If the elements of the population are suitably ordered we can attain an efficiency gain compared to SRS. A suitable ordering is given, e.g., if the units of the populations are ordered according to the sizes of the y values. On the contrary, if the ordering is bad, systematic sampling can actually generate worse precision than SRS. Such a case arises if the y values within the samples are more homogeneous, i.e. more similar, than in the population.

In many cases the population is partitioned into H disjunct strata $U_h, h = 1, \dots, H$, of size N_h , i.e. $U = U_1 \cup \dots \cup U_H$. Examples are the states of a country or the business divisions of a company. *Stratified selection* is defined by independent selection of n_h elements of each stratum $U_h, h = 1, \dots, H$. The advantage of stratified sampling compared to systematic random sampling can be enormous if the strata are more homogeneous – with respect to essential characteristics – than the population as a whole. The important question is how to allocate the **sample size** n to the strata.

A simple possibility is *proportional allocation* where

$$n_h = \frac{N_h}{N} \cdot n, \quad h = 1, \dots, H \quad (1)$$

Figure 1 Systematic sampling

i.e., the relative weight n_h/n of a stratum in the sample equals the relative weight N_h/N of the stratum in the population.

Optimal allocation is another allocation procedure, which, however, additionally requires information on variances $S_{yy}(h) = \sum_{i=1}^{N_h} (y_{hi} - \bar{Y}_h)^2 / (N_h - 1)$ of the unit characteristics $y_{h1}, \dots, y_{hN_h}$ in stratum $h, h = 1, \dots, H$. $\bar{Y}_h = \sum_{i=1}^{N_h} y_{hi} / N_h$ denotes the population mean of stratum $h, h = 1, \dots, H$. An example of an optimal allocation is the so-called Neyman allocation where

$$n_h = n \cdot \frac{N_h \sqrt{S_{yy}(h)}}{\sum_{g=1}^H N_g \sqrt{S_{yy}(g)}}, \quad h = 1, \dots, H \quad (2)$$

Since the computation of proportional or optimal allocation does not lead to integers, rounding rules must be taken into consideration.

Cluster sampling selects not single persons but clusters of persons, e.g. classes in a school. This kind of selection procedure is often chosen because of cost considerations. Usually, cluster sampling should be avoided if the clusters are homogeneous. Systematic sampling is a simple example of cluster sampling where the different clusters are defined by the possible samples and only one cluster has to be selected. SRS, stratified sampling, and cluster sampling are special cases of single-stage designs.

Stratified sampling and cluster sampling can also be understood as extreme examples of *multistage sampling*. In multistage sampling the population is divided up into partitions, which in this case are called *primary sampling units* (PSUs). Each PSU contains *secondary sampling units* (SSUs), and so on. The PSUs may be households and the SSUs the persons living therein. Two-stage sampling means that PSUs are selected by a random procedure, and SSUs are then randomly selected from these PSUs. This is a very common procedure in general social surveys.

In *two-phase sampling*, the first step consists of drawing a sample of the population and collecting easily available (inexpensive) information for these sample elements. In the next step, depending on this information a subsample of the sample is selected. For the elements of this subsample relevant but more expensive information can be collected. Inventory samples are examples for multiphase sampling.

In practice, sampling designs are generally very complex and are often a combination of stratified and multistage sampling. Usually, the probabilities of selection of the PSUs are not the same for all PSUs but depend on the size of the SSUs.

Estimation

After selecting the sample, the data are collected for example by interviewing, measuring, or observing. Once the data $d = \{(i, y_i) : i \in s\}$ are collected, the next question is how to estimate unknown quantities of the population such as the percentage of patients satisfied with a hospital service, the total expenses of a class of customers for a type of product, or the value of articles in an inventory. It is highly advisable to use an estimator that is adequate particularly with regard to the underlying sample design. The customary requirements for an adequate estimator are (nearly) unbiasedness and small mean square error or variance. If SRS is used, the sample mean $\bar{y}_s = \sum_{i \in s} y_i / n$ is a good estimator since it is unbiased for the population mean $\bar{Y}$. But if some auxiliary information $x_i, i = 1, \dots, N$, is available it should be also incorporated into the estimator. Denoting the population and sample mean of the x values by $\bar{X}$ and $\bar{x}_s$, respectively, the *ratio estimator* $(\bar{y}_s / \bar{x}_s) \cdot \bar{X}$ has smaller variance than the sample mean provided that the x and y values are nearly proportional for all elements of the population. If selection of the elements is done with unequal probabilities then the *Horvitz–Thompson estimator* $\hat{Y}_{HT} = \sum_{i \in s} y_i / \pi_i$ is design unbiased for the population total if all π_i are positive. The variance of the Horvitz–Thompson estimator is given by

$$V[\hat{Y}_{HT}] = \sum_{i,j=1}^N \frac{y_i y_j}{\pi_i \pi_j} (\pi_{ij} - \pi_i \pi_j) \quad (3)$$

The variance is a measure of quality of an estimator. Since it is unknown it has to be estimated from the sample. If the sample design is complex it can be very difficult to determine π_{ij} . As an example, the computation of the π_{ij} 's for cluster sampling with varying cluster sizes can be cumbersome if the clusters are ordered randomly and the selection of the clusters is done by an extension of systematic sampling. Then *resampling procedures* such as

jackknife or **bootstrap** are applied. If we are not interested in the whole population but in domains and the number of selected elements in a special domain is very small then the precision of a direct estimator such as the sample mean can be very poor. In such cases, techniques developed in *small area estimation* may help by borrowing strength from other sources. For example, prevalence of a particular disease may be adequately estimated from a study at a national level. If it is known that the prevalence of this disease is highly correlated with a set of predictor variables known at the state level then small area estimation can be used to obtain estimates on state level from the national data with greater precision than one would observe in state level, direct survey estimates. For an extensive treatment of small area estimation see [7].

Sample-Size Estimation

Before starting a survey the researchers must determine how many elements have to be selected. Besides the costs, it is necessary to clarify what magnitude of error can be tolerated. Consider the estimation of a population mean $\bar{Y}$ by an estimator $\hat{\bar{Y}}$. Usually, two objectives of controlling the absolute error by guaranteeing $P(|\hat{\bar{Y}} - \bar{Y}| \leq e) \geq 1 - \alpha$ and of controlling the relative error by guaranteeing $P(|(\hat{\bar{Y}} - \bar{Y}) / \bar{Y}| \leq e) \geq 1 - \alpha$ are distinguished. e is called the *margin of error* and $1 - \alpha$ the *confidence level*, say 0.95. To solve both problems at least approximately, **normal distribution** of the sampling distribution of $\hat{\bar{Y}}$ is assumed as well as the existence of a consistent variance estimator $\hat{V}(\hat{\bar{Y}})$, which allows building of **confidence intervals** on grounds of this approximation. In the case of SRS without replacement $P\left(|\hat{\bar{Y}} - \bar{Y}| \leq z_{1-\alpha/2} \sqrt{V(\hat{\bar{Y}})}\right) \geq 1 - \alpha$

with $V(\hat{\bar{Y}}) = 1/(N-1) \sum_{i=1}^N (y_i - \bar{Y})^2 (1 - \frac{n}{N})/n$, where $z_{1-\alpha/2}$ is the constant exceeded with probability $\alpha/2$ by the standard normal random variable. Since the variance of the estimator is unknown it must be estimated. If the objective is controlling the relative error then the *coefficient of variation* $CV_y = \sqrt{V(\hat{\bar{Y}})} / \bar{Y}$ has to be considered. The sample size necessary to achieve the relative error can be

derived as

$$n = \frac{\left(\frac{z_{1-\alpha/2} \cdot C V_y}{e}\right)^2}{1 + \frac{1}{N} \left(\frac{z_{1-\alpha/2} \cdot C V_y}{e}\right)^2} \quad (4)$$

If the a population mean $\bar{Y}$ is a proportion P , e.g., the proportion of unemployed, the sample proportion p has variance $V(p) = P(1 - P)/n \left(1 - \frac{n-1}{N-1}\right)$. If we do not have any idea about the magnitude of P we use the upper bound $V(p) \leq 1/4n \left(1 - \frac{n-1}{N-1}\right) < 1/4n$ where the first bound is adopted for $P = 0.5$. Controlling the absolute error we derive as necessary sample size

$$n = \frac{z_{1-\alpha/2}^2}{4e^2} \quad (5)$$

For example, if the margin of error is 3% we have to select 1067 elements to achieve 0.95 confidence level.

Confidence intervals and sample-size computations for complex sample designs can be found in [7].

Nonresponse

Sometimes, answers for some units of the selected sample are either totally or partly missing. This is referred to as *nonresponse*. Sources for *unit nonresponse* can be not-at-homes, refusals, unable to answer or not found. If a respondent answers some but not all the items, these missing items are referred to as *item nonresponse*. Nonresponse is a very serious problem and the treatment of which requires modeling assumptions. Therefore, it may be easier to deal with nonresponse in the framework of model-based inference. Usually, weighting procedures are applied for treating unit nonresponse and **imputation** methods for item nonresponse. **Calibration** estimators are

used very often nowadays to get a grip on the non-response problem, see [8].

Software

In the past, only specialized statistical software packages offered procedures for sampling. In the meantime, a lot of statistical software packages such as SAS, SPSS, Stata, or R enable the user not only to draw samples but also to analyze data collected by complex sampling procedures. The estimation of the *design effect*, defined formally by Kish in [4] as “the ratio of the actual variance of a sample to the variance of a simple random sample of the same number of elements”, is thereby very helpful. In this way the researcher is protected against error induced by the classical unrealistic assumption that data are independent identically distributed observations yielding confidence intervals that are too small and thus provoking a wrong interpretation of the output.

Adaptive and Spatial Sampling Designs

Introduction

Simple random sampling and other **basic sampling designs** belong to the class of *noninformative* designs. A sampling design is noninformative if the probability for sample selection does not depend on the characteristic of interest, say y . In contrast, a sampling design is *informative* if the selection of an element depends on the y values observed during the survey. A typical example for an informative sampling design is *sequential sampling* where the selection of a unit depends on the y values of the selected units preceding. In *adaptive sampling*, popularized by Thompson [1], units in the neighborhood of units in the sampling process with certain y values are sampled, too. Examples can be found in surveys assessing the abundance of rare species of animals or trees, in epidemiological surveys, in behavioral surveys [2], or in surveys on hazardous waste sites. A very new application of adaptive sampling is given in the field of web surveys [3].

In *spatial sampling* the characteristic of interest often is defined for a continuous region of space and time. Spatial sampling is an area of survey sampling applicable for sampling in two (or more) dimensions, e.g. sampling of fields.

Adaptive Sampling

In classical sampling we usually have noninformative designs such as simple random sampling. Here the selection probability is free of the characteristic of interest. Adaptive sampling designs are informative since an observed y value of a selected unit satisfies a special condition and the sampling process will then be finished or additional units will be added to the sample from its neighborhood. There are two kinds of designs, *sequential stopping designs* and *adaptive cluster designs*. Sequential stopping designs are not considered here.

The Sampling Process of an Adaptive Sample

In adaptive cluster sampling, in a first step an *initial sample* is selected. The initial sample is based

on a conventional sampling design such as simple random sampling, systematic sampling, cluster sampling, stratified sampling, or unequal probability sampling. Starting with the units of the initial sample, other units of the population in the neighborhood of the units in the initial sample are added. The final sample is called *adaptive sample*. One reason for such a procedure is that the units with special characteristics of interest are clustered.

The following simple example illustrates the whole sampling process.

Example 1 A certain species of plants accumulates in a study area. From the grid of 10×10 squares covering the study area, two squares are randomly selected (Figure 1a). For each selected square with at least one exemplar of the species, its neighbor squares (i.e., one common side) are added to the initial sample (Figure 1b). This process of sampling continues until no further exemplars are encountered.

Estimation

In adaptive cluster designs, conventional estimators used in noninformative designs are no longer unbiased and must be replaced by adequate estimators. These are presented in the section titled “Special Cases for the Initial Sample”.

Efficiency

Under certain conditions, adaptive strategies can be more *efficient* than simple random sampling of equivalent **sample size**. In [2] the following seven conditions are mentioned under which efficiency of adaptive cluster sampling possibly increases compared to conventional random sampling: (a) the within-network variance is a high proportion of the total population variance (i.e., the population is clustered or aggregated with high variability within aggregations); (b) the population is rare; (c) the expected final sample size with adaptive cluster sampling is not much larger than the initial sample size; (d) the costs of observing units in clusters or networks are less than the costs of observing the same number selected at random; (e) the costs of observing units not satisfying the condition are less than the costs of observing units satisfying the condition; (f) the condition for extra sampling may be based on an auxiliary variable easy to measure; and (g) an efficient estimator or Rao–Blackwell

Figure 1 (a) Initial sample quadrants. (b) Selected quadrants after augmentation

improved estimator is used with adaptive cluster sampling.

A Formal Description of Adaptive Cluster Sampling

Consider a population $U = \{1, \dots, N\}$ of size N . The population characteristic of interest is the *population total* $Y = \sum_{i=1}^N y_i$, or, equivalently, the *population mean* $\bar{Y} = Y/N$. A unit where a certain prespecified condition c that depends on its y value is not satisfied is called *edge unit*. In Example 1, there are 92 edge units. A *network* $C(i)$ consists of all units accessible from unit i by augmentation and by subsequently dropping all edge units. $C(i)$ depends on the selection method of the initial sample. An edge unit is also called a *singleton network*. Thus, in Example 1 there are 92 singleton networks, one network of size 2 and 7 networks of size 11. Defining

$$\bar{Y}_{C(i)} = \frac{1}{|C(i)|} \sum_{j \in C(i)} y_j \quad (1)$$

where $|C(i)|$ denotes the number of units in network, it is easy to see that

$$\sum_{i=1}^N \bar{Y}_{C(i)} = Y \quad (2)$$

Thus, estimating $\sum_{i=1}^N \bar{Y}_{C(i)}$ is equivalent to estimating the population total Y . If s is a sample, i.e., a subset of U , and $e(s, y_i | i \in s)$ is an unbiased

estimator of Y , then $e(s, \bar{Y}_{C(i)} | i \in s)$ is unbiased for Y , too. $C(s) = \cup_{i \in s} C(i)$ is an extension of s and is called an *adaptive sample*.

Closely related to adaptive sampling is *network sampling* where rare and clustered populations have to be sampled, e.g. in drug abuse research, and contact patterns are used for sampling. An overview of such link-tracing procedures is given in [4].

Special Cases for the Initial Sample

As already pointed out, the selection of the initial sample is an important component of the adaptive cluster sampling process. It determines the final adaptive sample as well as the estimator. In the section titled “Initial Simple Random Sample without Replacement”, the case will be considered when the initial sample is drawn by simple random sample without replacement. The section titled “Initial Unequal Probability Sampling” considers more general sample designs for the initial sample.

Initial Simple Random Sample without Replacement. Let π_i denote the probability that the initial sample intersects the network $C(i)$ for unit i . Then

$$\pi_i = 1 - \frac{\binom{N - |C(i)|}{n}}{\binom{N}{n}} \quad (3)$$

and the *Horvitz–Thompson estimator* $\hat{Y}_{HT}$ of Y is

$$\hat{Y}_{HT} = \sum_{i=1}^N \frac{y_i}{\pi_i} L_i, \quad (4)$$

$$L_i = \begin{cases} 1 & \text{if the initial sample} \\ & \text{intersects } C(i) \\ 0 & \text{otherwise} \end{cases}$$

Since π_i is constant for each unit i in the k th network, say $\pi_i = \tilde{\pi}_k, k = 1, \dots, K$, where K is the number of distinct networks in the population, we have

$$\hat{Y}_{HT} = \sum_{k=1}^K \frac{\tilde{y}_k}{\tilde{\pi}_k} \tilde{L}_k, \quad (5)$$

$$\tilde{L}_k = \begin{cases} 1 & \text{if the initial sample intersects} \\ & \text{kth network} \\ 0 & \text{otherwise} \end{cases}$$

where $\tilde{y}_k$ is the sum of the y values for the k th network.

If $\tilde{\pi}_{k\ell}$ denotes the probability that networks k and ℓ are both intersected, from classical theory of the Horvitz–Thompson estimator we get

$$E[\hat{Y}_{HT}] = Y \quad (6)$$

$$\text{Var}[\hat{Y}_{HT}] = \sum_{k=1}^K \sum_{\ell=1}^K (\tilde{\pi}_{k\ell} - \tilde{\pi}_k \tilde{\pi}_\ell) \frac{\tilde{y}_k}{\tilde{\pi}_k} \frac{\tilde{y}_\ell}{\tilde{\pi}_\ell}. \quad (7)$$

An unbiased variance estimator is given by

$$\widehat{\text{Var}}[\hat{Y}_{HT}] = \sum_{k=1}^K \sum_{\ell=1}^K \left(\frac{\tilde{\pi}_{k\ell} - \tilde{\pi}_k \tilde{\pi}_\ell}{\tilde{\pi}_{k\ell}} \right) \frac{\tilde{y}_k}{\tilde{\pi}_k} \frac{\tilde{y}_\ell}{\tilde{\pi}_\ell} \tilde{L}_k \tilde{L}_\ell \quad (8)$$

In Example 1 we get as an estimator for the total of the species of plants in the grid

$$\hat{Y}_{HT} = \sum_{k=1}^K \frac{\tilde{y}_k}{\tilde{\pi}_k} \tilde{L}_k = \frac{13}{0.13576} = 95.75893 \quad (9)$$

and for the variance estimation

$$\begin{aligned} \widehat{\text{Var}}[\hat{Y}_{HT}] &= \sum_{k=1}^K \sum_{\ell=1}^K \left(\frac{\tilde{\pi}_{k\ell} - \tilde{\pi}_k \tilde{\pi}_\ell}{\tilde{\pi}_{k\ell}} \right) \frac{\tilde{y}_k}{\tilde{\pi}_k} \frac{\tilde{y}_\ell}{\tilde{\pi}_\ell} \tilde{L}_k \tilde{L}_\ell \\ &= \frac{13^2}{0.13576} \left(\frac{1}{0.13576} - 1 \right) \\ &= 7924.90633 \end{aligned} \quad (10)$$

Initial Unequal Probability Sampling. Let $p(s)$ be the selection probability for the initial sample s , and let π_i, π_{ij} be the sample inclusion probabilities for population members i , respectively for pairs $i \neq j$. Following [5], we can use

$$e(s, \bar{Y}_{C(k)} | k \in s) = \sum_{i=1}^N \bar{Y}_{C(i)} b_{si} L_i \text{ with } E_p[b_{si} L_i] = 1 \text{ for all } i \quad (11)$$

as an estimator for Y . With

$$d_{ij} = E_p[b_{si} L_i - 1][b_{sj} L_j - 1], \alpha_i = \sum_{j=1}^N d_{ij} w_j$$

where $w_i (\neq 0)$ are constants, (12)

$$\begin{aligned} \text{Var}_p[e(s, \bar{Y}_{C(k)} | k \in s)] &= -\frac{1}{2} \sum_{i=1}^N \sum_{j=1}^N d_{ij} w_i w_j \\ &\quad \times \left(\frac{\bar{Y}_{C(i)}}{w_i} - \frac{\bar{Y}_{C(j)}}{w_j} \right)^2 \\ &\quad + \sum_{i=1}^N \frac{\bar{Y}_{C(i)}^2}{w_i} \alpha_i \end{aligned} \quad (13)$$

and an unbiased variance estimator is given by

$$\begin{aligned} &-\frac{1}{2} \sum_{i=1}^N \sum_{j=1}^N d_{ij} w_i w_j \left(\frac{\bar{Y}_{C(i)}}{w_i} - \frac{\bar{Y}_{C(j)}}{w_j} \right)^2 \frac{L_i L_j}{\pi_{ij}} \\ &+ \sum_{i=1}^N \frac{\bar{Y}_{C(i)}^2}{w_i} \alpha_i \frac{L_i}{\pi_i} \end{aligned} \quad (14)$$

provided all π_{ij} are positive.

Spatial Sampling

The increased incidence of thyroid carcinoma among children affected by the Chernobyl fallout, or more generally, the spatial distribution of contamination are examples where the spatial aspect plays an important role. If the objective is to estimate the contaminant concentration exceeding a fixed level, then the question of how to select a sample is somewhat different from the classical *finite-population approach* but related to the *superpopulation approach*. A good overview is given in [6].

The field of spatial sampling is split into two approaches, a model-based one and a design-based one. A closer look at both approaches is given in [7]. The main problem of spatial sampling is how to deal with the presence of spatial **correlation**, which is quite typical in problems concerning contamination. Adaptive cluster sampling as described in the section titled “Adaptive Sampling” is a design-based approach and is commonly used in a fixed-population approach. In a model-based approach the classical sampling framework is extended and the characteristic of interest is defined for a continuous region of space and time that can be described by a spatial stochastic process which has been elaborated in detail in [8].

The index set of the stochastic process corresponds to the unit labels $\{1, \dots, N\}$ of a fixed *target population*. The *sampling frame* is the list of *sampling units* that identifies every unit within the target population. The sampling units of the sampling frame in finite-population sampling now correspond to the collection of points or functions. More precisely, a spatial process is a real (or vector valued) process $\{Z(s) : s \in U\}$. The index set U is a region in space or in space and time.

The random variable $Z(s)$ represents the value of the characteristic of interest at s , a location or point. The total population is the integral of the process over a study region D . There exist various models that are widely used for Z , e.g.,

$$E[Z(s)] = \sum_{j=1}^p \beta_j F_j(s) \quad (15)$$

where the F_j are given functions and β_j are unknown parameters. In applications the underlying models take into consideration a spatial structure in so far that measurements at near sites tend to have more homogeneous, i.e., more similar values than more distant sites. Thus, the **covariance** function

$$C(s, t) = \text{Cov}[Z(s), Z(t)] \quad (16)$$

plays an important role. Usually $C(s, t)$ is assumed to be *stationary*, i.e.,

$$C(s, t) = c(s - t) \quad (17)$$

The function $C(s, t)$ is called *covariogram*.

If observations $Z(s_1), \dots, Z(s_n)$ at sites $s_1, \dots, s_n$ in the study region D are available it may be of interest to predict $Z(t)$ at a site in the study region D or to predict the integral of a linear or nonlinear function of the process over a subregion of D , e.g., the population total.

There exist several criteria to obtain optimal sites, e.g., the integrated **mean squared error** (IMSE) which minimizes

$$IMSE(s_1, \dots, s_n) = \int_D E \left[(\hat{Z}(t) - Z(t))^2 \right] dt \quad (18)$$

where $\hat{Z}(t)$ is a linear unbiased predictor of $Z(t)$. Examples are given in [9].

Selection and Validation of Response Scales

Theory and Levels of Measurement

Measurement (be it implicit or explicit) is defined as a set of rules for assigning either numbers or numerals to empirical properties of a concept under consideration (for example, employee satisfaction or customer loyalty).

In this context, *numerals* are numbers which are given a qualitative meaning (for example, 0 – male, 1 – female) according to the procedure specified by the rules. Both numbers and numerals facilitate the application of the tools of statistical analysis for descriptive, explanatory and/or predictive purposes [1].

If the rules for assigning either numbers or numerals to empirical properties of a concept under consideration are poor, measurement will be meaningless (which can be due to the problematic wording of survey questions, respondent **bias**, interviewer bias, etc.). Meaningful measurement is achieved only when it has high empirical correspondence with the concept the researcher plans to measure.

In the process of operationalization, the concept the researcher plans to measure is assigned a single variable, or a number of qualitative (categorical or discreet) and quantitative (numerical) variables. The former can be further classified into nominal and ordinal variables; the latter into interval and ratio variables according to the *level of measurement* or *measurement scale* [2].

The *nominal level* is the lowest level of measurement. At this level numerals or other symbols are used to classify objects or observations. Objects or observations with similar characteristics are assigned the same numeral or symbol. The only comparisons that can be made between objects and observations are those of (in)equality. Only one-to-one scale transformations are admissible for nominal variables.

The second level of measurement is the *ordinal level*. Very often, objects or observations are not only classifiable. They also exhibit some kind of relation, allowing for rank order. In addition to (in)equality, comparisons of “greater than” and “less than” can be made. Admissible scale transformations are strictly increasing.

At the *interval level* of measurement absolute differences can be calculated on top of comparisons of (in)equality, “greater than” and “less than”. Admissible scale transformations are any strictly increasing linear ones. Operations such as subtraction and addition are therefore meaningful. However, owing to the fact that interval scales have no natural or absolute zero, relative comparisons of magnitude (operations such as division and multiplication) are not allowed.

The *ratio level* of measurement is guaranteed with the existence of a natural or absolute zero (one for which a universal agreement on its location is achieved). Admissible scale transformations are any strictly increasing proportional ones. For variables with properties of the ratio measurement scale relative comparisons of magnitude are thus allowed – on top of comparisons of (in)equality, “greater than” and “less than”, as well as mathematical operations such as subtraction and division.

To summarize, the level of measurement determines which mathematical operations are possible on a variable, which, in turn, determine the tools of statistical analysis at researchers’ disposal (see Table 1).

Survey Measurement

General types of questions used in surveys are discussed in **Design and Testing of Questionnaires**. In this framework we will take a look at selected specific measurement tools applicable in the survey setting. Among them are list questions, category questions, ranking questions, and rating or scale questions.

List questions present the respondents with a list of responses from which to choose (see Example 1).

The response categories have to be defined clearly and meaningfully to all respondents. Also, all possible relevant options, which might be considered by any individual respondent, need to be accounted for. The response categories are very heterogeneous and may include options such as “yes/no” or “agree/disagree”; furthermore “don’t know” and “not sure”; “other” (in case the list of responses is not exhaustive); as well as “applies/does not apply” [3].

In contrast to list questions, *category questions* are designed with the goal of making respondents choose a single category. This is very useful when collecting data on behavior or attributes. The maximum number

2 Selection and Validation of Response Scales

Table 1 Scales of measurement^(a)

Scale	Acceptable comparisons	Illustrative examples	Acceptable measures of central tendency ^(b)
Nominal	$y_A = y_B$ $y_A \neq y_B$	Gender (male, female) Marital status (single, married, divorced, widowed)	Mode
Ordinal	$y_A > y_B$ $y_A = y_B$ $y_A < y_B$	Social class (lower, middle, upper) Level of agreement (disagree, neutral, agree)	Mode Median
Interval	$d = y_A - y_B$	Temperature	Mode Median Arithmetic mean
Ratio	$c = \frac{y_A}{y_B}$	Income Sales Number of employees	Mode Median Arithmetic mean Geometric mean

^(a)The measure of central tendency which gives the most useful information is printed in bold.

^(b) In behavioral sciences there exists a controversy over the use of mean for variables with the properties of the ordinal measurement scale. From the viewpoint of the measurement theory the use of mean for ordinal data is not permitted because the arithmetic operations are not meaningful on numbers which are not “true measurements” with predefined units of measurement. However, many behavioral scientists do calculate the mean for ordinal data under justification that although the interval difference between two ordinal ranks is not constant, it is often of the same order of magnitude (*see SERVQUAL Surveys* for further discussion).

of categories to be included is dependent on the type of questionnaire. Questions in self-administered and telephone questionnaires should have no more than five response categories [4]. Questions in structured interviews can have more categories provided that:

- a prompt card is used (see Example 2).
- the interviewer categorizes the responses (see Example 3).

Example 2 A category question: use of a prompt card

Example 1 A list question

Please tick the appropriate box(es) for services provided to you by the IT department in the past month.		
Description of service	Provided	Not provided
Hardware purchase		
Hardware maintenance		
Software licence		
agreement update		
Lost file(s) recovery		
Other (please specify):		

Which of the following search engines did you use during the last week? <i>Show respondent the prompt card with the logos of search engines. Read out the name of the search engines one at a time. Tick the appropriate box.</i>			
Search engine	Use	Did not use	Do not know
Google			
MSN search			
Yahoo			
Other (please specify):			

Example 3 A category question: interviewer categorizes the responses

How often did you go to the movies during the last 3-month period? <i>Listen to the respondent's answer and tick the appropriate box.</i>
Two or more times a week Once a week Less than once a week to fortnightly Less than fortnightly to once a month Less often

Example 4 A ranking question

Please number each of the factors listed below in order of importance to you in your choice of a car rental company. Number the most important 1, the next 2, and so on. If a factor has no importance at all, please leave blank.	
Factor	Importance
Opening hours	
24-h hotline	
Price	
Special offers	
Loyalty programme	
Other (please specify):	

Ranking questions are used when researchers want to find out the relative importance of a single response item (for example, of a product feature or the factor determining a purchase decision) in comparison to other applicable response items. Such questions should have very clear instructions and not more than seven or eight items to be ranked as the respondents are capable of ranking accurately only when they can see or remember all items. In a telephone survey, where respondents can only rely

on their memory, there should be a maximum of only three or four items to rank [5].

Example 5 A rating or scale question

For the following statement please tick the box that matches your view most closely. <i>I fear about my job security.</i>
Disagree completely Disagree Neither disagree nor agree Agree Agree completely

When analyzing respondent opinions, researchers usually rely on *rating or scale questions*. The most commonly used is the Likert-style rating scale in which the respondent is asked how strongly he or she (dis)agrees with a statement or a series of statements. The level of (dis)agreement is usually measured on a scale that has from 4 to up to 10 points.

A typical Likert-style scale applied to measure service quality or employee satisfaction would include five points:

1. completely disagree
2. disagree
3. neither disagree nor agree
4. agree
5. completely agree.

A lot of controversy is involved with the issue of whether the number of points should be even (without the neutral middle point) or odd. However, there is a widespread agreement that the number of negative and positive response options for a single question should be in balance.

Two most common variations of the Likert-style rating scale are the numeric rating scale (see Example 6) and the semantic differential (see Example 7). The numeric rating scale is used if the researcher wants the numbers to reflect the feeling of the respondent. The semantic differential is applicable in consumer research projects focused on determining underlying consumer attitudes. Here, the respondent

4 Selection and Validation of Response Scales

is asked to rate a single object or idea on a series of bipolar rating scales described by a pair of opposite adjectives.

Example 6 The numeric rating scale

For the following statement please circle the number which matches your view most closely. <i>This packaged holiday was . . .</i>											
1	2	3	4	5	6	7	8	9	10		
Poor value for money										Good value for money	

Example 7 A semantic differential

On each of the lines below place an x to show how you feel about the quality of lectures in the course on business ethics.		
Good handouts	----	Poor handouts
Boring	----	Inspiring
Appropriate use of multimedia	----	Inappropriate use of multimedia

Reliability and Validity of Measurement

Whenever we attempt to measure something, we want our measures to be reliable and valid, capturing what they are supposed to capture. The observed measurement score might reflect the true score as well as the influence of other factors. These might be *stable personal characteristics* (one person might be more generally talkative than another), *transient personal factors* (such as moods), as well as *situational factors* (time pressure, mode of questionnaire administration, data entry errors, etc.).

Reliability is defined as the measurement instrument's consistency. It tells us whether the same measures yield the same results on different occasions.

Validity is concerned with the following questions:

- whether the research findings are really what they appear to be about (whether we measure what we intended to – the so-called internal validity);
- whether the research findings support the intended interpretation of the variables (the so-called construct validity);
- whether the research findings can be generalized at the level of statistical population from which the sample was drawn (the so-called statistical conclusion validity);
- whether the research findings can be generalized beyond the level of statistical population from which the sample was drawn (the so-called external validity).

Reliability does not imply validity: a reliable measure might be consistent in measuring something yet that something is not necessarily what the measure is supposed to be measuring.

In the survey setting, threats to reliability include participant error, participant bias, interviewer error, as well as interviewer bias. Some of the important threats to validity are [6]:

- history (related traumatic past experiences of the respondents may have misleading effects on research findings);
- testing effects (respondents may realize how to use the measurement instrument to their advantage);
- mortality (respondents may drop out of the study and thus jeopardize generalizability of research findings);
- maturation (change of attitudes, opinions, and knowledge of respondents during the study duration may affect research findings);
- ambiguity about the causal direction between the researched concepts (the famous egg/hen problem makes for a difficult interpretation of research findings).

In order to estimate reliability, researchers can apply either single-administration or multiple-administration methods. Two single-administration methods (the split-half method and the internal consistency method) and two multiple-administration

methods (the test-retest method and the alternate forms method) are briefly described in the following paragraphs.

The *split-half method* estimates reliability by treating each of two or more parts of a measurement instrument as a separate scale. It is based on the Spearman–Brown prediction (or prophecy) formula:

$$r_{xx'} = \frac{2r_{oe}}{1 + r_{oe}} \quad (1)$$

where $r_{xx'}$ is the reliability of the original test and r_{oe} is the reliability coefficient obtained by correlating the scores of the odd statements with the scores of the even statements.

The *internal consistency method* correlates each scale item with the total score, giving the researcher a tool for identifying the items to drop (those with the lowest correlations) and the items to keep (those with the highest correlations). The method is based on the Cronbach's α which measures the extent to which the scale items are connected. The α can be calculated in several ways; the formula for the standardized α is

$$\alpha = \frac{N \cdot \bar{r}}{(1 + (N - 1) \cdot \bar{r})} \quad (2)$$

where N is the number of scale items and $\bar{r}$ is the average of all (Pearson) **correlation** coefficients between them. The value of α will generally increase with increased correlations between the scale items. In behavioral sciences an acceptable level of α is 0.70 or higher, demonstrating an acceptable level of reliability.

The essence of the *test-retest method* is administering the measurement instrument to the same group of persons at two different points in time, and then calculating the correlation between the two sets of observations (scores). The reliability coefficient is thus based on the Pearson product-moment correlation coefficients between two subsequent administrations of the same measure.

In the framework of the *alternate forms method* the researcher develops two alternate versions of a measurement instrument, which are supposed to be equivalent in their ability to measure the desired concept. Both versions are administered to the same group of people, and correlation coefficients are calculated between two sets of observations (scores). The reliability coefficient is thus based on the Pearson product-moment correlation coefficients between two

different forms of measure administered at a single point in time.

Triangulation

In the process of measurement, data can be obtained either in formal or informal settings and can represent verbal (oral and written) as well as nonverbal acts and/or responses [7]. This combination (formal *versus* informal setting; verbal *versus* nonverbal acts/responses) accounts for the following major methods of **data collection**: library research, observation studies, survey research, and experimental research.

Should researchers wish to study nonverbal acts in an informal setting, they might decide on using participant observation as a method of data collection. Should the focus be on verbal responses in a structured setting, a standardized questionnaire might be the data collection tool of choice. Between these two opposite poles there exists a number of other type of setting/type of response combinations.

Each data collection method has its advantages and disadvantages. It is an established fact that research findings are affected by the nature of the selected data collection method. As pointed out by Fiske [8]:

"Each method [of data collection] is ... one discriminable way of knowing" (p. 62).

In other words, by exclusively using one method of data collection researchers run the risk to discover only one piece of the whole puzzle.

In order to minimize the possible effect of the chosen data collection method on the validity and/or scope of the research findings, researchers can use two or more methods of data collection to test hypotheses and measure variables. Discovering different pieces of the puzzle and putting them together by applying different methods of data collection is thereby the essence of *triangulation*. Are the findings of different data collection methods consistent with one another, this greatly increases the validity of research.

Design and Testing of Questionnaires

Questionnaire and Questionnaire Surveys

Questionnaire is the most frequently used **data collection** tool of survey research. It is constructed with the goals of measuring attitudes, opinions, perceptions and knowledge, and comparing or explaining practices or behavior. In other words, it helps researchers finding out what a selected group of respondents know, think, or feel – something which cannot be done by means of an observation study, or an experiment.

Any form of a questionnaire survey is an interaction between a researcher and a respondent [1]. In a self-administered questionnaire survey with no interviewer-respondent interaction, the researcher speaks to the respondent directly through a questionnaire. In an interviewer-administered questionnaire survey it is the interviewer who reads the words of the researcher to the respondent (in the process he or she might introduce the so-called interviewer **bias** into the research). In both cases it is paramount that every respondent is asked the questions in exactly the same way as the others. Additionally, the same question should mean the same thing to every respondent.

The most frequently used types of questionnaire surveys are presented in Table 1.

Table 2 summarizes the most important characteristics of personal, telephone, mail and on-line questionnaire surveys.

Two factors that determine the questionnaire design requirements to the largest extent are the form

of the questionnaire (paper *versus* electronic), and the mode of questionnaire administration (interviewer-*versus* self-administered questionnaire). We look at them more closely in the next section.

Questionnaire Design

Advance information on the subject matter of the questionnaire survey is usually obtained by means of a *focus group* discussion. A focus group helps researchers to gather data related to the feelings and opinions of a group of people with similar experiences or involved in a similar situation in a neutral setting. Listening to other group members' views encourages focus group participants to voice their own opinion, which would be less accessible without a group interaction [5]. This interaction facilitates coverage of all issues related to the chosen topic, which sets the boundaries of the subsequent questionnaire survey. Although the focus group data are mostly of qualitative nature, they do provide the researcher with a guide to the most pressing matters to be addressed, and the most relevant questions to be asked, in the questionnaire.

The *general questionnaire design principles* pertain to individual questionnaire items regardless of the questionnaire form and mode of administration. According to these principles, each questionnaire item should:

- be explicitly related to goals and objectives of the research;
- be understood by all respondents in the same way;
- ask for information which can be either immediately recalled by respondents or retrieved from their records;

Table 1 Types of questionnaire surveys^(a)

Interviewer-administered questionnaire		Self-administered questionnaire	
On paper	On screen	On paper	On screen

^(b) Computer-assisted personal interviewing.

^(c) Computer-assisted telephone interviewing.

- be constructed in such a way as to prevent introduction of a respondent and interviewer bias into research;
- be formatted in a way that minimizes data entry errors.

If applied consistently, these general principles should guarantee that in practice, every questionnaire functions as planned by the researcher.

Additionally, *specific questionnaire design principles* should be followed for different questionnaire forms and modes of administration.

A *self-administered questionnaire* should provide the respondent with clear explanations and instructions for every questionnaire item or group of items. Also, contact information (a toll-free phone number or an e-mail address) should be provided in case of any respondent queries. This information can be either a part of an accompanying letter (for example, in case of a mail survey) or part of the respondent address at the beginning of an on-line questionnaire.

An *interviewer-administered questionnaire* needs to be designed in such a way that it caters to the needs of both the interviewer and the respondent. To insure that all interviewers ask the same question in the same manner, standards for interviewer behavior, question presentation and probing should be established in advance during the interviewer training sessions which should take place regardless of the length and complexity of the questionnaire.

When designing a *paper questionnaire*, special attention should be paid to easiness and convenience of questionnaire completion on one, as well as easiness and convenience of data entry on the other hand. Clearly linking questions and responses, keeping designated response spaces in the right-hand column area, using different typesets for instructions and questions, and so on facilitates both.

When designing a *questionnaire in the electronic form*, easiness and convenience of questionnaire completion are the sole most important concerns as the recording of responses and data entry take place simultaneously. Speed and reliability of modern internet connections give questionnaire designers a lot of room for development of attractive interfaces and – in case of a self-administered questionnaire – use of multimedia.

Sufficient time and resources should be allocated to questionnaire translation and testing should a survey be conducted in different languages.

Types of Questions

Survey questions take one of two primary forms. *Open questions* require respondents who are both capable and willing to use their own words when answering. This means that answers to open questions must be catalogued, coded and interpreted which makes the use of open questions less applicable in large-scale surveys but very important whenever respondents' own words are essential. The latter is very often the case in the initial phase of questionnaire design (where the number and heterogeneity of possible response options to a single question are assessed). Consider the question in Example 1.

Example 1: An open question and possible answers

Question: What kind of car are you driving?

Answer 1: A red one Answer 2: A really fast

one Answer 3: Old Answer 4: I don't own a car

Answer 5: A Renault

Closed questions have a preselected number of response options which should be mutually exclusive. They must be known in advance which makes closed questions much more difficult to write than open questions.

Closed questions tend to be more efficient and reliable when trying to obtain information from large groups of respondents. They seem to be preferred by respondents who are either unwilling or unable to express themselves while being surveyed [6].

While closed questions mean more work in the questionnaire design phase, they produce standardized data which are easily statistically analyzed.

When designing survey questions, researchers should be aware of respondent characteristics. A *set of general rules* which should be followed in the question design process includes a number of items [5–8]:

- *Explain the purpose of the questionnaire to all respondents – and then ask purposeful logically related questions.* For instance, in a survey about a theme park experience respondents will not expect questions about the next elections.

4 Design and Testing of Questionnaires

- *Ask precise and unambiguous questions.* Questions can be labeled as precise and unambiguous if a number of respondents agree on the words used without prompting.
- *Use time periods that are related to the importance of the question.* Periods of a year or more can be used for major life events (birth of a child, divorce, death of a parent). Periods of a month or less should be used for less important issues.
- *Do not use slang, colloquial expression, jargon, specialist language, and abbreviations.* Whenever possible (unless you are dealing with a very homogeneous group whose members share a special language), stick to conventional wording and rely on standard grammar, punctuation, and spelling.
- *Avoid using biasing words and phrases.* Words such as “nigger” or “abortion”, and phrases such as “freedom fighters”, might trigger emotional responses, or even prejudices which have little to do with the issues addressed by the survey. Biasing words and phrases may differ in different cultures, which is why all questions must be reviewed and pilot tested before they are used.
- *Avoid asking negative questions.* Negative questions such as “Do you agree with the statement that the European Union shouldn’t have the authority to intervene in the member states’ internal affairs?” tend to be misunderstood and/or misinterpreted by respondents because they require an exercise in logical thinking.
- *Avoid asking offensive or insensitive questions.* They might cause embarrassment or pose a threat to the respondent. If included in a mail or on-line questionnaire, these questions negatively influence the rate of response. If at all, such questions should be asked in a face-to-face interview – and even in that case they should be related to past indiscretions rather than the respondent’s present behavior.
- *Avoid the use of leading questions.* It is against the ethical code of research to steer respondents toward the preferred response option.
- *Ask only one question at a time.* In other words, avoid double-barreled questions such as “Do you think the customers and employees will benefit from the newly introduced company initiative?”
- *Do not be afraid to ask value-laden questions.* Sometimes this might be the only way to encourage respondents to give a “true” rather than a

socially acceptable response. However, use this type of questions with caution – you do not want the respondents to get annoyed and either not answer the question or answer it inaccurately.

- *Do not be afraid to ask factual questions.* However, do not degrade them to questions which merely perform the function of a memory test. Also, avoid factual questions which require the respondents to perform calculations.

By adhering to these general rules, you should be able to keep your questionnaire as short as possible, while including all the questions required in achieving your research goals.

Note that it is often best to use questionnaire items that have been tested in the past and found to yield good results. A number of readily available standard measurement instruments are available for different topic areas in a broad number of disciplines (see **SERVQUAL Surveys** for a discussion of the **SERVQUAL**, a rating scale to measure perceived service quality). They facilitate survey comparability in time and across countries, but might limit the scope of the planned research project because of the boundaries associated with question wording and order.

Questionnaire Testing and Piloting

In order to test and evaluate a questionnaire, a wide range of methods can be used. Some (e.g., an expert panel or a peer evaluation) are more applicable in the early stages of questionnaire design, others (e.g., a pilot study) should be used prior to the broad questionnaire distribution. The most important ones are briefly discussed in the following paragraphs.

Both *peer evaluation* and an *expert panel* serve the same purpose: to provide the researcher with preliminary feedback concerning the draft version of a questionnaire. The feedback can be of technical nature and/or pertaining to the issues of content. It serves as a basis for the first few questionnaire revisions.

Although peer and/or expert reviews can be very effective in producing good quality questionnaires, it is also extremely useful to pretest the questionnaire on individuals who are representative of the population to be surveyed. A *split panel test* is an experimental comparison of two or more

versions of the same questionnaire. These are used to evaluate the impact of question order, question wording, and data collection method on survey results.

Cognitive one-to-one interviews are conducted by specially trained interviewers with the following two objectives: to probe the respondents' understanding of individual questions, and to examine the respondents' thinking processes as they provide their answers. Cognitive interviews thus help researchers understand and eliminate potential problems associated with question wording.

A *pilot study* is the most comprehensive and therefore also the most expensive of applicable questionnaire testing and piloting methods. Its scope is broader than that of a split panel test or a cognitive interview because it provides researchers with the feedback on all steps of the data collection process.

Tools of statistical analysis should also be mentioned when it comes to questionnaire design and testing. **Correlation** coefficients might be used to reduce the number of highly related questions. Cronbach's α might be calculated to find out how well a set of items (or variables) measures a single hypothesized unidimensional latent construct. Structural equation modeling can be applied to assess the measurement

error stemming from questionnaire design – and to correct for it [9].

IRENA OGRAJENŠEK

Data Management in Survey Sampling

Introduction

Traditional **data collection** methods include postal mail surveys, telephone, and face-to-face surveys. Recently, new technologies have led to a rapid emergence of a wide array of new data collection methods. This entry focuses first on new technologies related to data collection. It subsequently turns its attention to technological advances in the field of data management.

New Technologies Used to Collect Data

Interviewer-Administered Surveys

Paper-and-pencil telephone and face-to-face surveys were largely replaced by their computerized counterparts in the 1970s [1]. These well-established computer-assisted survey information collection (CASIC) methods are *computer-assisted telephone interviewing* (CATI) and *computer-administered personal interviewing* (CAPI), respectively.

Recent advances involve miniaturization of input devices in CAPI surveys (using smaller laptop computers such as pen computers and PDAs [2]) and keeping up with changing technology use patterns in society. One such particularly important change is the emergence of mobile-phone-only households. “Dual frame” survey designs have been proposed to keep those households covered in CATI surveys, but these designs introduce additional chances of selection for individuals and households, which have both landline and mobile telephone numbers (*sampling bias*). Statistical correction procedures are necessary to address this problem.

Self-Administered Surveys

Even before a sizable portion of the general population possessed computers, computerized self-administered data collection was implemented in CAPI surveys. Whenever necessary, but usually when sensitive questions were asked, the interviewer could turn over the laptop to the respondent to fill in

that part of the survey questionnaire by himself. This is believed to increase the respondent’s sense of privacy, which would increase the level of honesty of the reports [3]. This type of data collection has been termed *computer-assisted self interview* (CASI). Partly to deal with respondents with limited reading skills, *audio computer-assisted self interview* (ACASI) was developed. A recorded voice reading out the question is played to the respondent (usually through earphones). If no aural cues are provided, one can speak of *video computer-assisted self interview* (VCASI), and reserve *CASI* as a broader term encompassing both ACASI and VCASI. A telephone version of audio computer-assisted self interview (*T-ACASI*) also exists [4]. A similar survey type is *interactive voice response* (IVR). Selected respondents are asked to call a toll-free phone number or are transferred to the survey by the interviewer who has recruited them. Respondents listen to prerecorded questions, voice-read answers, response options, and instructions for which numbers they can use for their response.

Computerized self-administered questionnaires (CSAQ) are sent to respondents in electronic form. Respondents fill them out on their computers and send the responses back to the survey organization. An early form was the *disk by mail* (DBM) system, in which the questionnaire was stored on a floppy disk and sent by postal mail. In contrast, *e-mail surveys* send the questionnaire (either as attachment or in-line) by e-mail. The World Wide Web allows surveyors to put *web surveys* (“forms”) on the Internet (*computer-assisted web interviewing*, CAWI). The web survey address is communicated through e-mail, other on-line communication (such as posting the web survey address in newsgroups, banners on web sites, etc.), or off-line communication (e.g., web survey addresses printed in off-line media). With the arrival of *digital*, *interactive*, and *web TV*, similar surveys could be implemented without requiring respondents to own a computer.

Since mobile phones and PDAs can also connect to the Internet using protocols such as WAP (wireless application protocol) or GPRS (general packet radio service), web surveys can also be completed using these devices. Nonetheless, these devices represent some limitations such as a small screen, low resolution, or slow Internet connections. Recently, *SMS* (*short message service*) surveys have also started to emerge. These surveys target mobile phone

users and typically ask only a small number of questions since SMS messages are limited to a relatively small number of characters.

New technologies may speed up data collection and reduce costs, but some problems do arise. New data collection methods such as web or mobile phone surveys in many countries face the problem of nonexistent *sampling frames*, which adequately cover the general population (coverage error) as well as the problem of low *response rates* (nonresponse error). Convenience samples based on volunteer panels are sometimes used. Efforts have been undertaken to develop strategies to overcome generalization problems associated with convenience samples, for instance, by using randomly drawn *calibration samples* and application of propensity score adjustment (PSA) procedures [5].

Concern also exists about the *quality of data* collected with emerging technologies. Web surveys, for instance, generate higher levels of unit nonresponse, item nonresponse, do-not-know responses, and acquiescence than CATI surveys [6]. With self-administered questionnaires, usability is important to ensure sufficiently high **data quality** levels. New technologies have facilitated data collection needed to evaluate usability such as eye tracking [7] and keystroke registration [8]. New methods, particularly CSAQs, typically also reach relatively distinct population segments (younger, more highly educated Caucasians with higher income levels who are comfortable using new technologies), decreasing the representativity of these samples. Methodological procedures (e.g., offering incentives) and statistical correction procedures (e.g., PSA) are needed to alleviate these problems.

One proposed strategy to combine advantages of new methods with advantages of more traditional methods is to combine different survey modes. *Mixed-mode survey* designs deploy different survey modes either simultaneously or sequentially to follow-up nonrespondents from a previous mode. Although mixed-mode surveys are rapidly gaining popularity, a serious drawback is that they may produce mode effects [9].

New Technologies Used in Data Management

Fieldwork organizations rely on automated systems to manage the interviewing system and the collected

data. At the risk of oversimplifying, interviewing system management refers primarily to *case management*. This includes sample management, on-line call scheduling (in CATI systems), automated call history record keeping, maintenance and reporting of call outcome data, transfer cases to other interviewers, preparation of datasets, and so on [10]. With the increasing popularity of mixed-mode surveys, case management systems must also be capable of transferring sample cases from one survey mode to another.

Recent advances eliminate the need of interviewers to be physically present in the research organization to connect to the system. New systems allow telephone interviewers to operate from their own homes or CAPI interviewers to conduct surveys in the homes of the respondents, while still being connected to the central system, e.g., through the Internet.

Recently, much attention is being paid to *process data*. These data can be used to monitor the fieldwork process. If e.g., data on contact attempts and their outcomes are continually registered and fed into the computerized data management system, data collection protocols can be adapted during the fieldwork. Typically, the aim is to reduce error on an array of relevant variables for which the distribution in the study population is known (e.g., age, type of residence). Research on such “responsive survey designs” is still in the exploration phase [11].

Other aspects of data management are *data coding* and *data editing* (see “**survey data processing**”). These steps can be at least partially automated [12]. Recent advances in data editing include definition and use of a so-called abstract data model of a survey and software that automatically derives from this model the functional form of edits and statistical criteria to clean data [13]. New systems allow both data coding and data editing to be performed during the interview. Such integration is associated with a certain risk in that original data may be lost, eliminating the possibility to evaluate and if necessary correct the automated procedures.

DIRK HEERWEGH

Processing of Survey Data

Introduction

After the data are collected, a number of processing steps must be performed to convert the **survey data** from its raw and unedited state to a verified and corrected state that is ready for analysis and/or dissemination to the users. If the data were collected by *paper and pencil* (PAPI) methods, they will have to be converted into a computer-readable form. Responses to open-ended questions may need to be classified into some number of categories using a coding scheme so that these responses can be tabulated. In addition, a number of operations may be performed on the data to reduce survey errors and missing items.

For example, the data may be “cleaned” by eliminating inconsistencies and addressing unlikely responses (e.g., *outliers*). Survey weights may be computed that account for unequal selection probabilities. These weights may be further refined by a series of “postsurvey adjustments” that are intended to reduce coverage error **bias**, nonresponse bias, and sampling variance. Some survey variables (for example, household income) may have numerous missing values and values may be *imputed* for them. Following these steps, the data contents file should be well documented. Data *masking* and *de-identification* techniques may also be conducted on the file to protect the confidentiality of the respondents. The next section provides a brief overview of these data processing activities.

Overview of the Data Processing Steps

The data processing steps vary depending on mode of **data collection** for the survey and technology available to assist in data processing. The steps involved for processing PAPI questionnaires will be discussed initially. These steps include the following:

- scan editing
- data capture
- data editing
- coding
- file preparation
- data documentation
- analysis.

The steps for *computer-assisted interviewing* (CAI) methods are essentially the same except that the data entry step is not necessary since the data are already keyed into the computer by an interviewer.

The PAPI Questionnaire

The PAPI questionnaire is used to collect information for the variables under study. Some questions corresponding to these variables are closed-ended requiring the interviewer (or respondent) to check a box representing a response alternative. For example, marital status may be coded as “1 = single”, “2 = married”, “3 = divorced”, “4 = widow/widower”, and “5 = never married”. For open-ended questions, a free-format response is written in a blank field on the questionnaire. For example, a response to the question “What is your occupation?” may be “I am a security officer for a bank” or “I am a barber. I cut hair.” The questionnaire may also involve branching to skip around questions that do not apply. These legitimately skipped items need to be distinguished from items requiring a response that were not answered by the respondent. The latter type of skip constitutes item-missing data, which is often addressed by the subsequent processing steps.

Scan Editing

Scan editing is an operation involving several steps. First, as questionnaires are received by the survey organization, they are coded as received into the receipt control system and inspected for obvious problems such as blank pages or missing data for key items that must be completed in order for questionnaires to be usable. In *interviewer-assisted* surveys, the questionnaires that are rejected as being incomplete by this process may be sent back to the interviewers for completion. For mail surveys, the questionnaires might be routed to a telephone *follow-up* process for completion. In cases where there is no follow-up of nonrespondents, the questionnaires may be passed on to the next data processing step (i.e., data entry). Ultimately, questionnaires that are not minimally completed will be coded as nonrespondents due to incomplete data. Also as part of the process, questionnaires may be grouped into small batches called *work units* to facilitate the subsequent processing steps.

Data Capture

In *data entry* or *data capture*, the paper questionnaire responses are converted into computer-readable form (i.e., digitized). Data can be entered manually using keying equipment or automatically by using scanning or optical character recognition devices. To use the latter methods, messy questionnaires may have to be copied onto new, clean forms so that the scanner can read them properly. Keying usually involves some form of **quality control** verification. For example, each questionnaire may be keyed independently by two different keyers. Any discrepancies between the first and second keyings are then rectified by the second keyer. Alternatively, **acceptance sampling** methods (typically, a **single sampling plan**) may be applied to each work unit. Here, only a sample of questionnaires within each work unit is rekeyed. If the number of discrepancies between the two keyings exceeds some threshold value, the entire work unit would be rekeyed. Because of these verification methods, the error rate associated with keying is usually quite low for closed-ended responses – less than 0.5%. However, for verbal responses such as names and addresses, the error rates are substantially higher – 5% or more [1].

Data Editing

Editing is a process for verifying that the digitized responses are plausible and, if not, modifying them appropriately. Editing rules can be developed for a single variable or for several variables in combination. The editing rules may specify acceptable values for a variable (e.g., an acceptable range of values) or acceptable relationships between two or more variables (e.g., an acceptable range for the ratio of two variables). Typically editing identifies entries that are either definitely in error (called *critical edits*) or are highly suspicious of being in error (called *query edits*). Corrective measures must be taken for all critical edits while various rules may be applied to determine which query edits to address in order to reduce the cost of the editing process. This approach is sometimes referred to as *selective editing* [2].

Some surveys specify that respondents should be recontacted if the number of edit failures is large or if key survey items are flagged as in error or

questionable. In this manner, missing, inconsistent, and questionable data can be eliminated by the respondent's input. However, this is not always done either to save costs or due to the impracticality of respondent recontacts. In that case, values may be inserted or changed by means of deducing the correct value based upon other information on the questionnaire or from what is known about the sample unit from prior surveys. Consistency checks, selective editing, deductive editing, and other editing functions can be performed automatically by specially designed computer software.

Coding

Coding is a procedure for classifying open-ended responses into predefined categories that are identified by numeric or alphanumeric code numbers. For example, there may be thousands of different responses to the open-ended question “What is your occupation?” To be able to use this information in subsequent analysis, each response is assigned one of a much smaller number (say 300–400) code numbers, which identify the specific occupation category for the response. To make occupation categories consistent across different surveys and different organizations, a standard occupation classification (SOC) system is used. A typical SOC codebook may contain several hundred occupation titles and/or descriptions with a three-digit code number corresponding to each. In most classification standards, the first digit represents a broad or main category, and the second and third digits represent increasingly detailed categories. Thus, for the response “barber”, a coder consults the SOC codebook and looks up the code number for “barber”. Suppose the code number is 411. Then the “4” might correspond to the main category “Personal Appearance Workers” 41 might correspond to “Barbers and Cosmetologists”, and 411 to “Barber”. In *automated coding*, a computer program assigns these code numbers to the majority of the cases while the cases that are too difficult to be accurately coded by computer are coded manually.

File Preparation

The file preparation step results in an analysis file that serves as the output file and the output file is

used to produce statistics and analyses. This step consists of a number of activities including *weighting*, *imputation*, *postsurvey weighting adjustments*, *statistical disclosure analysis*, and *data suppression*. First, weights have to be computed for the sample units. Often the weights are developed in three steps. First, a base weight is constructed, which is the inverse of the probability of selection for a sample member. Second, the base weight is adjusted to compensate for nonresponse error, and third, further adjustments of the weights might be performed to adjust for frame coverage error depending on availability of external information. These so-called *post-survey adjustments* are intended to achieve additional improvements in the accuracy of the estimate.

Imputation is a process that replaces missing responses with values that may be treated just like other responses in the subsequent analysis. It has been shown that imputation reduces the biases in analysis due to item nonresponse. A common method is hot-deck imputation, which fills in missing values using corresponding values from similar people in the same dataset. Cold-deck imputation, by contrast, selects donors from another dataset.

Finally, if the data file is to be released to the public, a statistical disclosure analysis may be performed to determine the risk that a sample member on the file could be identified by an *intruder* on the basis of a sample member's data. This may involve estimating the probability that an individual in the file can be *reidentified* (i.e., his or her identity can be discovered with certainty) by an intruder. If this probability is unacceptably high, then various techniques are available to suppress or mask some responses to avoid identity disclosure and to protect the confidentiality of the sample member (see [3] for an overview of these methods).

Data Documentation and Analysis

The final processing step is data documentation in which a type of data file users manual is created. This document describes the methods used to collect and process the data and provides detailed information on the variables on the file. For example, each variable on the data file might be linked to one or more questions on the questionnaire. If variables were combined, recoded, or derived, the steps involved in creating these variables is described. The documentation might also include information regarding

response rates for the survey, item nonresponse rates, reliability estimates, or other information on the total **survey error** of key variables.

The new technologies have opened up many possibilities to integrate these data processing steps [4]. Therefore, the sequence of steps might be very different from those described above for some surveys. For example, it is possible to integrate data capture and coding into one step; likewise, data capture and editing can be integrated with coding. It is also possible to integrate editing and coding with data collection through the use of CAI technology. The advantage of this type of integration is that inconsistencies in the data or insufficient information for coding can immediately be resolved with the respondent. This reduces follow-up costs and may also result in better information from the respondent. Many other possibilities for combining the various data processing steps exist. The goal of integration is to increase the efficiency of the operations while improving **data quality**.

Data Quality and Data Processing

As is clear from the previous discussion, the data can be modified extensively during data processing. Hence, data processing has the potential to improve data quality for some variables while increasing the error for others. Unfortunately, knowledge about the errors introduced in data processing is very limited in survey organizations and consequently such errors tend to be neglected. Often operations are sometimes run without any particular quality control efforts and the effects of errors on the overall accuracy as measured by the **mean squared error** (MSE) are often unknown except perhaps for national data series of great importance.

As an example, although editing is intended to improve data quality, it misses many errors and can even introduce new ones. Automation can reduce some of the errors made by manual processing, but might introduce new errors. For instance, in optical recognition data capture operations, the recognition errors are not uniformly distributed across digits and other characters, which can introduce systematic errors (i.e., biases). For these reasons, quality control and quality assurance measures should be a standard part of all data processing operations. For more information on data processing steps and their contributions to survey error, see [5].

PAUL P. BIEMER

Statistical Analysis of Survey Data

Introduction

After **data collection** and entry, survey data need to be prepared for analysis and analyzed. The data preparation stage involves three important steps: data formatting, data editing, and computation of survey weights. The data analysis stage involves the choice of relevant statistical tools according to the measurement scale properties of survey variables. Both stages are discussed in the following sections.

Data Preparation Stage

The data preparation stage starts with the decision on *how to format the data* in view of available computing facilities and analytical software. Analysis of survey data often involves two or more different units of analysis. Consequently, the data file needs to provide for the nested hierarchical structures (e.g., employees within a company, members of a household within a household unit, etc.).

An important part of data formatting procedures is the construction of a code – a set of rules translating survey answers into numerals and numbers (for a definition of numerals *see Selection and Validation of Response Scales*). Codes should be unambiguous. If designed appropriately, they help researchers minimize errors in the data analysis phase.

The following is a set of the commonsense principles to facilitate the **coding** process [1]:

- In the database, response options should be numbered in the same order they appear on the questionnaire.
- Whenever possible, codes should fit numbers in the real world (for example, “a 20-year-old” should be coded as “20”).
- Consistency should be maintained when assigning numerals (for example, “0” should be assigned to all male respondents, “1” to all female respondents in a survey).
- It should be ensured that the codes differentiate between the categories such as “don’t know”, “does not apply”, and “missing”.

Existing coding schemes such as standard classifications (classifying products, activities, occupations, etc.) should be used wherever possible because they save time, they are usually well tested, and they allow comparisons of research results with other surveys [2].

Following the decision on data format the next step is *data editing*; *see Processing of Survey Data*. Errors in survey responses (for example, inconsistent responses or responses that fall outside the range of possibilities) need to be identified and dealt with.

A special challenge is presented by items for which answers have not been obtained. The so-called **item nonresponse problem** occurs when a sampled unit cannot be contacted, does not respond to the request to participate in a survey, or refuses to answer to a particular survey question owing to fatigue, sensitivity, lack of knowledge, or other factors [3].

Item nonresponse results both in a reduced **sample size** and in the possibility that the remaining data set is biased. The problem might be overcome through the process of assigning values for the missing responses by a number of **imputation** methods that have been steadily developed since the 1980s.

If the proportion of missing values is small, a single imputation might be quite reasonable. This is rarely the case in real life, which is why Rubin’s multiple imputation (a **Monte Carlo** technique in which the missing values are replaced by $m > 1$ simulated versions, where m is typically small, ranging from 3 to 10) gained such popularity [4]. Following the process of imputation, each of the simulated complete datasets is analyzed by standard methods. The results are combined to produce estimates and **confidence intervals** that incorporate missing-data uncertainty.

Originally, the use of multiple imputation was limited to large data files from censuses and sample surveys. However, with the advent of new computational methods and software that support the process of multiple imputation, this technique has become increasingly attractive for researchers in the biomedical, behavioral, and social sciences [5].

The final step of data preparation involves the *computation of survey weights*. These are computed for all units of analysis. The construction of weights starts with determining the selection probabilities of sample units. The initial (base) weights for sampled

units are then computed as the inverses of the sample units' selection probabilities and adjusted to compensate both for the eligible nonrespondents and for the nonrespondents with unknown eligibility status. Further adjustments are possible if researchers want to make the adjusted weighted sample distributions for identified key variables conform to known distributions of these variables available from external sources [6–8].

Data Analysis Stage

Survey data analysis has two distinguishing characteristics in comparison to standard statistical analysis [6]:

- First, as already stated, there exists the need to use survey weights to compensate for unequal selection probabilities, nonresponse, and noncoverage. The danger of not using weights lies in the possibility of producing distorted estimates of population values.
- Secondly, there exists the need to compute sampling errors for survey estimates in such a way that a survey's complex sample design is accounted for. While the standard statistical analysis assumes unrestricted sampling, many surveys employ stratified multistage sampling. Given that, in general, sampling errors for estimates from a stratified multistage sample are larger than those from an unrestricted sample of the same size, the application of the standard formulas will overstate the precision of the estimates [9–11]. This means that standard statistical software packages produce invalid **standard error** estimates for survey estimates. It is therefore recommended that researchers resort to the use of special survey analysis software packages such as (in alphabetical order) CENVAR, Epi-Info, IVEware, PC-CARP, SAS, STATA, SUDAAN, and WasVar [11].

Often, the nature of survey data analysis is descriptive, e.g., in the form of means, percentages, and/or totals. The results may be presented in a tabular or graphical form to facilitate understanding and interpretation.

Whereas in narrow technical terms the estimates are usually very simple (the proper use of

weights being the researchers' only concern), important methodological challenges have to be dealt with in advance. The important issues are the definition of a construct like "customer satisfaction" that should be measured, operationalization of the construct, and survey units specification. The goal is to make sure that the construct to be measured is measured in the most suitable way.

For complex constructs (for example, poverty, wealth, or literacy), aggregate measures (indices) are often constructed with the help of multivariate statistical methods (e.g., factor or cluster analysis).

While the production of descriptive estimates remains the predominant form of survey data analysis, examination of relationships between variables (with special emphasis on analysis of **causality**) also merits research attention. Statistical techniques applied to this effect are the analysis of association, contingency, and **correlation**, as well as regression analysis. Based on the type of the model variables, the researcher decides whether to use linear regression (in case of continuous cardinal variables), Poisson regression (for count data), or logistic regression (in case of categorical variables); see [8, 12].

Survey Error

Introduction

In survey samples, the primary objective usually is to estimate unknown population quantities, such as population means or totals. The estimates invariably do not exactly equal the population values, i.e., there are survey errors. This chapter describes typical sources of survey errors. The context is estimating a population quantity with a randomly selected sample (*see Internal and External Quality Measures; Sampling Designs in Surveys; Adaptive and Spatial Sampling Designs*) of a population.

Survey Errors

Survey errors can be classified in two categories, non-sampling and sampling errors. Nonsampling errors arise due to unplanned mistakes in the **data collection** process, whereas sampling errors arise due to the variation from measuring only a subset of the population. Often nonsampling errors are difficult to detect and quantify. In contrast, sampling errors can be controlled and quantified. Indeed, many published surveys report results only in terms of estimates and sampling errors, without assessments of nonsampling errors (*see Survey Quality and Survey Ethics*). The magnitude of survey errors is affected by the amount of resources available, deadlines for releasing data products, and ethical issues in data collection and dissemination. Although important, these issues are not discussed here.

When describing the effects of survey error, survey methodologists use the terms *bias* and *variance*. To fix ideas, let θ be the population quantity of interest, and let $\hat{\theta}$ be the estimator of θ . The bias of $\hat{\theta}$ is $\text{Bias}(\hat{\theta}) = E(\hat{\theta}) - \theta$, where $E(\hat{\theta})$ is the expected value of $\hat{\theta}$. The variance of $\hat{\theta}$ is $E((\hat{\theta} - E(\hat{\theta}))^2)$. Survey samplers seek to design data collection systems that yield estimates with near-zero bias and small variance. In general, nonsampling errors increase bias, whereas sampling errors increase variance. The combined effect of both is called the *total survey error*, often represented by the mean square error, $MSE(\hat{\theta}) = E((\hat{\theta} - \theta)^2) = \text{Bias}^2(\hat{\theta}) + \text{Variance}(\hat{\theta})$.

We now describe the main sources of survey error. As a framework, we use the categorization

of survey errors presented by Biemer and Lyberg [1]. These include specification error, measurement error, coverage or frame error, mode effect error, nonresponse error, and process error. This is a typical categorization in the research literature; for example, similar errors are described by Weisberg [2].

Specification Error

Specification error arises when the survey does not address the main concepts of interest, instead providing information on different concepts. For example, the organization funding the survey might want to learn about the total income available to families, but the questionnaire asks families about total income from employment. This could render the results useless or even misleading for the concept of interest. Specification error generally results from poor communication between those who define the goals of the survey and those who design the questionnaire. Specification errors can be avoided when both parties carefully review the survey goals and questionnaire.

Measurement Error

In any survey, it is crucial that the collected data actually measure what is intended. This is challenging when surveys require responses from people. First, respondents may interpret words and questions differently than intended by the survey designer. If so, respondents could be answering effectively different questions; this complicates interpretations. Second, respondents may not be able to answer questions because they do not understand them or do not have the necessary information. The former problem arises with technical questions, and the latter with questions about events in the past, which people may remember imprecisely. Third, respondents may be unwilling to answer questions accurately, because they fear their answers will appear socially undesirable.

Determining the extent and impact of measurement error is difficult. The best approach to dealing with measurement error is to tackle the problem at the beginning of the survey process. For example, survey organizers can convene focus groups of potential respondents to evaluate whether people interpret and are able to answer the questions as intended, and alter question wording appropriately based on the feedback from these groups (*see Design and Testing of Questionnaires*). An extensive literature exists for

2 Survey Error

designing questions that generate reliable information. See, for example [1–6].

Coverage Error

The goal of random sampling is to select units that, after suitable weighting, represent the target population of interest. This breaks down when the sampling frame, i.e. the list from which the random sample is selected, does not include all units in the target population. When units missing from the frame have different characteristics than the rest of the target population, survey estimates may be biased. For example, suppose a target population is all people in a city. Sampling phone numbers listed in the telephone book excludes people with unlisted numbers or without telephones. When these people differ from people in the phone book on important characteristics, the sample does not represent the entire population and survey estimates are biased.

The sampling frame might be deficient because of the units it includes rather than excludes. Some units on the frame might not be eligible for the survey. When used for **estimation**, these units might bias results. Some units might be on the frame multiple times, which gives them a higher chance of being selected than other units. Without correction for differential probabilities of inclusion, estimates can be biased.

The key to avoiding coverage error is to use an accurate sampling frame with a one-to-one correspondence with units in the population. Such frames can be expensive to develop or verify. An alternative strategy is to put together multiple frames, without necessarily removing duplicates, in hopes of covering the target population. Using multiple frames requires adjusting the survey weights. One option for checking the frame for undercoverage is to obtain an external file with records that should be in the population and the frame, and estimate the fraction on the file that are missing from the frame. See [1, 2] for more discussion of coverage bias.

Mode Effect Error

Typically **survey data** on individuals are collected through mail or e-mail questionnaires, telephone interviews, or personal interviews. Face-to-face or telephone interviews can influence responses. For example, interviewers might present themselves or

ask questions in ways that lead respondents to be differentially accurate or truthful in their answers. In mail surveys, respondents may have difficulty following the instructions of the questionnaire, for example not adhering to complicated instructions for skipping questions.

Mode effect error is best reduced in the survey design stage. Many survey organizations reduce interviewer effects by training them not to deviate from standardized protocols. Consistency is further improved by computer-aided personal/telephone interviewing (*see Data Management in Survey Sampling*), especially for complicated questionnaires. See [1, 2] for examples of and strategies for dealing with mode effect error.

Nonresponse Error

Ideally, all measurements are recorded for every unit in the sample. Often this is not the case. Some units may not respond to the survey at all, and others may respond only to some items. When the respondents' characteristics differ from those of the nonrespondents, estimates could be biased. For example, people who are satisfied with a product might not respond, whereas those who are unsatisfied might respond. Even without such differences, nonresponse increases variances because estimates are based on fewer observed values than originally intended.

There are many strategies for handling nonresponse. Strategies for reducing its impact at the design stage include, among others, developing clear and to-the-point questionnaires, providing monetary or other incentives for survey completion, providing assurance of confidentiality, and planning for follow-up with nonrespondents (*see Processing of Survey Data*). After data collection, the estimates can be adjusted for nonresponse. Common approaches include modifying the survey weights and **imputation** of missing values. For details on methods for handling nonresponse, see [7].

Process Errors

The final stage of data collection involves turning the raw data into usable files. This process usually involves record checks and edits, recodes, or categorizations of responses, and creation of survey weights (*see Processing of Survey Data*). All these

steps are subject to error, which may be difficult to find when data processing is done with automated procedures. The literature on process errors is not extensive. One recommendation is to establish **quality management** practices (*see Survey Quality and Survey Ethics*) to ensure minimal errors in data processing.

Sampling Errors

Every sample survey is subject to sampling error, since different samples comprise different records. Fortunately, when selection is done randomly, survey analysts can estimate sampling errors with variances. The most common method for doing so is the design-based paradigm, in which estimates of variance are computed using mathematical formulas induced by the probabilities of selection (*see Statistical Analysis of Survey Data*). For example, in a simple random sample with no nonresponse, the estimated variance of the sample mean, $\bar{y}$, is $(1 - n/N)s^2/n$, where n is the **sample size**, N is the population size, and s^2 is the sample variance of the values of y in the data. There are many texts describing sampling error estimates, one classic being [8].

Concluding Remarks

Estimating the total impact of nonsampling and sampling errors is challenging. Unless a gold standard

file is available, in which nonsampling errors are known to be small, there are no standard approaches for estimating the total survey error. Developing such approaches is an area of ongoing statistical research.

JEROME P. REITER

Survey Quality and Survey Ethics

Introduction

Various producers of statistics have devoted considerable efforts to improve the quality of their products. Traditionally, surveys are annotated with quality descriptions providing the clients with support to interpret the results. Furthermore, there can be studies on the quality of the entire sample survey, called *quality reports*. The clients often need more profound information on the organization, applied procedures and processes as well as the products. Thus, the approach is changing from a mere focus on product quality to total **quality management** (TQM).

This article describes various perspectives of survey quality, starting from traditional reporting and ending up with recent more comprehensive quality approaches.

Survey Errors and Quality

One of the main issues in ensuring good quality in surveys is to avoid different types of errors which are discussed by **Survey Error**. Survey organizations are very keen in avoiding errors in all survey processes to assure better quality. However, since the errors are inevitable, their magnitude and effects should be evaluated and reported. Estimated standard errors for parameter estimates are probably the oldest quality measures for sample surveys. Standard errors and other estimates based thereupon, like coefficients of variation or **confidence intervals**, have been calculated from statistical samples since the rise of survey methodology in the 1940s and 1950s.

Besides the sampling errors some authors pointed out, quite early, the roots of other types of errors. For example, Mahalanobis [1] gives subtle examples of various error sources in statistical work process. Similarly, the errors in coverage and those created by nonresponse were taken into consideration. **Survey error** concepts, ending up with the most comprehensive one, the total survey error containing both the sampling and nonsampling errors, are analyzed in various textbooks (see e.g., [2]). All sources of error except the basic sampling error can induce systematic

errors which may distort the results. The magnitude of systematic errors should therefore be analyzed and reported using proper statistical methods (see e.g., [3, 4]) even though a profound mean square error (MSE) **estimation** may not be amenable.

The cost aspect is important. Costs affect all stages of survey process: sampling design, planning and preparation of material needed for a survey, **data collection** methods, communication with respondents, data editing and cleaning, as well as analyzing and reporting, see [2, 5]. Survey quality improvements are always subject to cost constraints.

Reporting of Quality

The first official recommendation of presenting survey quality aspects was published by the United Nations [6]. The UN papers laid down much of the basic ideas applied even today. A fundamental requirement is that all characteristics having an impact on **data quality** should be known to the users.

Types of Reports

There are generally three types of reports describing survey quality. The first type are *comprehensive reports* which contain all aspects of a survey starting from the background information, describing all processes, errors and ending in a comparison with other data sources. The US Federal Committee on Statistical Methodology [7] calls them *analytical reports* and the preparation of such a report requires investigation of the whole process. They are often not targeted at laymen, but rather at researchers and professional peers.

The second type are *brief reports* (or quality descriptions) often included as a separate chapter or box in the publication. These are short and meant to give the reader an overall view of the quality, with some key indicators and recommendations to users.

The third type, *quality profiles*, are understood to present a view on how different quality aspects change with time. For example, Eurostat gives short quality profiles for a vast set of structural indicators and indices, and grades their quality by three categories [8]. On the other hand, the National Center for Education Statistics presents a profound quality profile using the total survey error model of three waves of large school surveys in the United States [9].

In general, **time series** are a useful method of giving information on the development of various quality aspects, for example, nonresponse rates.

The quality reports should always indicate how the errors have been adjusted and give advice to the users on possible limitations when using the data.

Quality Indicators

Many proposals have been put forward for a set of indicators to be provided when reporting quality. Preferably, the indicators should cover all relevant aspects of quality. The coverage errors should be evaluated, standard errors and other measures of precision of parameter estimates should always be included. Unit nonresponse rate(s) and, if possible, the effect of unit nonresponse on certain key parameters should be investigated. Proposals for a standardized way of informing about unit nonresponse exist (see e.g., [10, 11]), but so far there is no generally accepted form of reporting, except in certain internationally coordinated surveys. However, the situation is much more unsatisfactory concerning the other indicators of quality. Eurostat has its own standard set of indicators [12] and the US Federal Committee proposes some others [7].

Metadata and Documentation

The increasing dissemination through internet creates a challenge to all survey organizations. The users should be provided with similar quality information, which is embedded directly into the statistical tables and databases. Metadata and documentation systems store and provide information on the various aspects of quality: statistics production and outputs as well as identification of areas for improvement.

There are metadata standards like the special data dissemination standard (SDDS) [13], or statistical data and metadata exchange (SDMX) [14] which partly fill the need. Although the standards are developing fast, there are many issues to be solved before the metadata systems are so complete that a user may explore all quality and process issues as deeply as is needed. Therefore, new inventions are to be expected in standardizing statistical metadata.

Professional Ethics Related to the Quality Issues

Ethical Codes

Professional ethics is a very important constituent with respect to quality of surveys and statistics, in general. It sets the general guidelines for the activity of each statistician or researcher. On this issue, we refer to the code of the International Statistical Institute [15]. It consists of the following topics:

1. obligations to the society
2. obligations to funders and employers
3. obligations to colleagues
4. obligations to subjects

with a number of references. Many agencies in the field of official statistics have created their own codes. Besides the code for professionals, we must mention the guidelines for authorities. Here, the main reference is the United Nations Fundamental Principles for Official Statistics [16].

Marketing and Opinion Research

The marketing research communities have focused on quality and ethical issues for a long time. The first international code dates back to the late 1940s, and the current code was accepted jointly by the International Chamber of Commerce and World Association of Research Professionals [17]. The code focuses especially on the rights of customers to obtain impartial and objective results, addressing also the rights of respondents, professional responsibilities, and the mutual requirements of survey organization and their clients. Similar codes of professional ethics exist in many market research organizations and associations, e.g., [18].

Total Quality Management

Recently, many survey organizations have introduced a holistic approach to quality, often in the form of TQM. It is specifically visible in official statistics, where either national or international requirements have put pressure to accept some form of systematic and standardized practices, both in work processes and output. As a consequence, the organizations have given declarations to promote quality (e.g.,

[19]), accepted quality criteria in the form of policy, guidelines, current best methods, and so on [20], and established a program to realize those policies [21]. Examples of those approaches include the European Statistics Code of Practice [22] or the Data Quality Assessment Framework of the International Monetary Fund (IMF) [23].

TQM is based on dividing the quality concept into three main categories: operational environment, work processes and outputs. Each main category contains many different things to be assessed and measured. Finally, the organization must have a proper way to analyze feedback from customers and other sources, and to learn from the experiences. Introducing a TQM-based quality management is a time-consuming process, and it will often change the whole organization. In addition, it requires good documentation of all phases of processes, self-assessments, as well as internal and external auditing procedures.

In spite of apparently similar main headings, the realization of the policy can vary substantially. As an example, the comparison of the European Statistical Code of Practice and the IMF Data Quality Assessment Framework reveals that they share many common items, but differ in some others [24].

The renowned international standard of the ISO 9000 family [25] is not very common among survey organizations, rather national certification standards have been applied in market research. A recent quality standard ISO 20252 for market, opinion, and social research [25] is intended to overcome that problem. Although it is mainly devoted to the market research community, the systematic approach can also be applied to academic research and official statistics. The main titles of the 20252 standard include *Quality management system requirements*, *Managing the executive elements of research*, *Data collection*, *Data management and processing*, and *Report on research projects*. The standard is still in the introductory phase and the certification procedures are to be developed.

KARI DJERF

SERVQUAL Surveys

Explanation of SERVQUAL

Service quality is often analyzed using rating scales to assess individual service attributes. The most widely used and most carefully scrutinized rating scale is SERVQUAL (the name stands for SERVICE QUALity).

The scale is a result of a systematic ongoing study of service quality that begun in 1983 [1–5]. The model defines quality as the difference between customer perceptions and expectations with regard to quality of delivered service. The respondents are asked to answer two sets of questions dealing with the same subject, one set at a general level (e.g., quality of service in financial institutions), and one for a company in question (e.g., quality of service in bank XYZ). The first (general) set of questions are quality expectations (E_i), the second (specific) set are quality perceptions (P_i) as shown in Table 1.

Respondents choose from a modified Likert scale which measures intensity of agreement or disagreement with any given statement. Response options range from “strongly agree” and lesser levels of agreement to “neutral” (neither agree nor disagree) and lesser levels of disagreement to “strongly disagree”. It has to be pointed out that SERVQUAL is based on the assumption of the Likert scale’s cardinal nature. In real life, however, one person’s “complete satisfaction” might be less than another’s “partial satisfaction” (for a more in-depth discussion of Likert scale related critique of SERVQUAL see the section titled “Reexamination and Criticism of SERVQUAL”).

For each of the 22 items (service attributes), a quality judgment can be computed according to the following equation:

$$\text{Perception}(P_i) - \text{Expectation}(E_i) = \text{Quality}(Q_i) \quad (1)$$

Quality is poor if expectations exceed perceptions and vice versa. On the other hand, if low customer expectations are met, quality does exist.

The SERVQUAL score (perceived service quality) is obtained by the following equation:

$$Q = \frac{1}{22} \sum_{i=1}^{22} (P_i - E_i) \quad (2)$$

The $P_i - E_i$ gap scores can be subjected to an iterative sequence of item-to-item **correlation** analyses, followed by a series of factor analyses to examine the dimensionality of the scale using the oblique rotation, which identifies the extent to which the extracted factors are correlated.

The original SERVQUAL scale had 97 items that resulted in ten service quality dimensions. The presently established 22-item scale shown in Table 1 has five quality dimensions defined as follows:

- *tangibles*: physical facilities, equipment, and appearance of personnel;
- *reliability*: ability to perform the promised service dependably and accurately;
- *responsiveness*: willingness to help customers and provide prompt service;
- *assurance*: knowledge and courtesy of employees as well as their ability to convey trust and confidence;
- *empathy*: individual care and attention that company provides its customers.

However, as discussed in the section titled “Reexamination and Criticism of SERVQUAL”, empirically identified five-factor structure cannot be found in all service industries.

Reexamination and Criticism of SERVQUAL

Although SERVQUAL has been widely used in business-to-business and business-to-customer settings, this does not mean the scale has not been subject to reexamination and criticism. The main objections to SERVQUAL pertain to the object of measurement, length of the questionnaire, timing of questionnaire administration, use of the Likert scale, use of ($P_i - E_i$) difference scores, generalization of service quality dimensions, and the static nature of the model. Let us take a closer look at each of them.

2 SERVQUAL Surveys

Table 1 An overview of SERVQUAL dimensions and expectation as well as perception items

Quality dimension	Expectations (E_i)	Perceptions (P_i)
Tangibles	Excellent companies will have modern-looking equipment. The physical facilities at excellent companies will be visually appealing. Employees of excellent companies will be neat in appearance. Materials associated with the service (such as pamphlets or statements) will be visually appealing in an excellent company.	XYZ has modern-looking equipment. XYZ's physical facilities are visually appealing. XYZ's employees are neat in appearance. Materials associated with the service (such as pamphlets or statements) are visually appealing at XYZ.
Reliability	When excellent companies promise to do something by a certain time, they will do so. When customers have a problem, excellent companies will show a sincere interest in solving it. Excellent companies will perform the service right the first time. Excellent companies will provide their services at the time they promise to do so. Excellent companies will insist on error-free records.	When XYZ promises to do something by a certain time, it does so. When you have a problem, XYZ shows a sincere interest in solving it. XYZ performs its service right the first time. XYZ provides its services at the time it promises to do so. XYZ insists on error-free records.
Responsiveness	Employees of excellent companies will tell customers exactly when services will be performed. Employees of excellent companies will give prompt service to customers. Employees of excellent companies will always be willing to help customers. Employees of excellent companies will never be too busy to respond to customer requests.	Employees of XYZ tell you exactly when the service will be performed. Employees of XYZ give you prompt service. Employees of XYZ are always willing to help you. Employees of XYZ are never too busy to respond to your requests.
Assurance	The behavior of employees of excellent companies will instill confidence in customers. Customers of excellent companies will feel safe in their transactions. Employees of excellent companies will be consistently courteous with customers. Employees of excellent companies will have the knowledge to answer customer questions.	The behavior of XYZ's employees instills confidence in you. You feel safe in your transactions with XYZ. Employees of XYZ are consistently courteous with you. Employees of XYZ have the knowledge to answer your questions.
Empathy	Excellent companies will give customers individual attention. Excellent companies will have operating hours convenient to all their customers. Excellent companies will have employees who give customers personal attention. Excellent companies will have the customers' best interests at heart. The employees of excellent companies will understand the specific needs of their customers.	XYZ gives you individual attention. XYZ has operating hours convenient to you. XYZ has employees who give you personal attention. XYZ has your best interests at heart. Employees of XYZ understand your specific needs.

Adapted after A. Parasuraman, L.A. Berry and V.A. Zeithaml, "Refinement and Reassessment of the SERVQUAL Scale", 1991, pp. 446–449.

Object of measurement.

It is not clear whether the scale measures service quality or customer satisfaction [6].

Length of the questionnaire.

The SERVQUAL questionnaire is too long. It could be shortened by elimination of expectation scores (see discussion under *use of $(P_i - E_i)$ difference scores* for more details), elimination of certain items (those without the clear mode) and/or fusion of the interrelated dimensions of *reliability*, *responsiveness* and *assurance* into one dimension called *task-related receptiveness* [7, 8].

Timing of questionnaire administration.

The main issue here is whether to distribute the questionnaire before or after the service experience [9, 10]. In other words, should expectations be solicited before the service experience, or away from the actual point of service delivery and unrelated to an encounter? Some researchers compromise by collecting their data after the service experience at the actual point of service delivery [7]. Consequently, they fear that this might have loaded their results toward performance, while those of other researchers might have been loaded toward expectations.

Use of the Likert scale.

Several issues are problematic here. Firstly, the structure of the Likert scale should be noted. SERVQUAL authors use a seven-point scale, while in many replication studies a five-point scale is adopted to increase response rate and response quality.

Secondly, the already mentioned fact that SERVQUAL is based on the assumption of the Likert scale's cardinal nature should not be overseen. Furthermore, once the respondents have marked the extreme point and want to express an even stronger opinion on the next item, this cannot be reflected in the answer anymore, since the maximum score has already been given [11]. Unfortunately, the researcher has no tool to assess the levels of interrespondent reliability, agreement, and consensus.

Finally, from the viewpoint of statistical analysis, some authors argue that none of these problems matter as long as the answers are normally distributed [6].

However, in practice, the majority of SERVQUAL surveys tend to result in highly skewed customer responses. Hence, an average rating based on the arithmetic mean of the customer responses is likely to be a poor measure of central tendency, and may not be the best indicator of service quality.

Use of $(P_i - E_i)$ difference scores.

Ambiguous definition of expectations in the SERVQUAL model seems to be a major problem. Increasing $P_i - E_i$ scores may not always correspond to increasing levels of perceived quality which impugnes theoretical validity of the SERVQUAL's perceived quality framework [12–14].

Generalization of service quality dimensions.

An empirically identified five-factor structure cannot be found in all service industries. Only the existence of the *tangibles* dimension is confirmed in all replication studies, in which the number of distinct service quality dimensions otherwise varies from one to nine [15]. It seems that the dimensionality of service quality might be determined by the type of service a researcher deals with [16].

The static nature of the model.

There exists a number of long-term service processes (such as education) where both perceptions and expectations (and consequently quality evaluations) change in time. For these service processes, a dynamic model of service quality should be developed [17].

Generalizations of and Alternatives to SERVQUAL

In order to assess its general applicability, the SERVQUAL scale has been replicated in many different service industries both in business-to-business and business-to-customer markets.

Many of the replication studies question the value and purpose of two separate datasets (perceptions and expectations). Some researchers suggest that it might be better not to use difference scores since the factor structure of the answers given to the questions about expectations and perceptions, and the resulting difference scores, are not always identical [18–21]. Additionally, research

shows that performance perception scores alone give a good quality indication. Therefore, a modified SERVQUAL scale using only performance perceptions to measure service quality (called SERVPERF, which stands for SERVICE PERFORMANCE) has been proposed [20].

A three-component measurement model including perceptions, expectations, and perceived importance ratings, or weights of service attributes has also been suggested [10]. A rationale for this model is the following: while customers might expect excellent service on each attribute, all of the attributes involved may not be equally important to them. However, it seems that the inclusion of perceived importance ratings does not substantially improve the explanatory **power** of the model.

An attempt to operationalize service quality as a multiplicative linear compensatory function of performance and importance ratings is also described in the literature [22]. However, when practically applied, this model does not surpass SERVQUAL in performance.

The only approach that, to date, seems to outperform SERVQUAL is SERVPERF, the performance-only measure of service quality.

Assignable Cause

In process control and improvement, it is effective to discern the variation of process characteristics into variation due to *chance causes* (noise) and due to *assignable causes* (signal). Assignable causes (called *special* causes by W.E. Deming, and *sporadic events* by J.M. Juran) leave traces in the data in

the form of nonrandom patterns, which enables their identification. Chance causes are a collection of multiple influences, none of which dominate the others, whose cumulative effect is often conceptualized as normal uncorrelated variation. Chance causes are called *common causes* by Deming, and *chronic* by Juran. Assignable causes are often regarded as exogenous to the system, whereas chance causes are considered endogenous.

Autocorrelation Function

Introduction

In quality and reliability engineering studies, time-series observations (*see Time Series Analysis*) are often statistically correlated. A typical example is a set of observations taken on a process variable (like temperature) in regular time intervals, where the (fixed) elapsed time between consecutive observations is relatively short. Due to the natural inertia of the process, observations that are close together will probably tend to locally covary (*see Covariance*), even when both the process mean and the process variance do not vary over time (the process is stationary). In this article it is assumed that the time series is stationary (*see Time Series Analysis*). The covariation between pairs of observations in the time series that are equally distant from one another may be captured by their typical autocorrelation (this is the usual Pearson correlation (*see Correlation*); since it is calculated between observations belonging to the same sample of observations, it is denoted as *autocorrelation*). The autocorrelation between the observation at time period t and the one at time period $t + k$ is named *autocorrelation at lag k* , and is denoted ρ_k (due to stationarity, ρ_k is independent of t). The autocorrelation function displays the autocorrelation as a function of k . It plays a central role in time-series modeling. In the section titled “Definitions and Some Formulae” we define the autocorrelation function and the partial autocorrelation function. In the section titled “Estimation”, estimation procedures are discussed.

Definitions and Some Formulae

The Autocorrelation Function

Let z_t denote an observation taken on a stationary process at time t . Let the mean be $E(z_t) = \mu$, and denote the variance by $E[(z_t - \mu)^2] = \sigma_z^2$ (due to the assumed stationarity, both the mean and the variance do not depend on t). The covariance (*see Covariance*) between z_t and z_{t+k} (namely, between any two process values that are k time intervals

apart) is called *autocovariance at lag k* , and it is calculated by

$$\gamma_k = \text{cov}[z_t, z_{t+k}] = E[(z_t - \mu)(z_{t+k} - \mu)] \quad (1)$$

The *autocorrelation at lag k* is the correlation between z_t and z_{t+k} :

$$\rho_k = \frac{E[(z_t - \mu)(z_{t+k} - \mu)]}{\sqrt{E[(z_t - \mu)^2]E[(z_{t+k} - \mu)^2]}} = \frac{\gamma_k}{\gamma_0} = \frac{\gamma_k}{\sigma_z^2} \quad (2)$$

(due to stationarity, the variances of z_t and z_{t+k} are the same, σ_z^2). Obviously, $\rho_0 = 1$.

The expression in equation (2) does not express ρ_k as an explicit function of k . If such a function exists, it will be denoted as *the autocorrelation function* of the process. For example, for a first-order autoregressive model (*see Time Series Analysis*), the autocorrelation function is $\rho_k = \phi_1^k$ ($k \geq 0$), where ϕ_1 is a certain parameter. If no explicit function in k is available, however one can calculate individual autocorrelations, then the *plot* of the autocorrelation coefficients, ρ_k , as a function of the lag, k , is called *the autocorrelation function*, and it is denoted by the set notation $\{\rho_k\}$. Since $\rho_k = \rho_{-k}$, the autocorrelation function is symmetrical around $k = 0$.

The Partial Autocorrelation Function (for AR(p) Models)

One category of time-series models is the group of autoregressive models (*see Time Series Analysis*). For an autoregressive process of order p , AR(p), it may be shown that the autocorrelation function may be given by the difference equation (refer to [1], p. 56)

$$\rho_k = \phi_1 \rho_{k-1} + \phi_2 \rho_{k-2} + \cdots + \phi_p \rho_{k-p}, \quad k > 0 \quad (3)$$

where $\{\phi_i\}$ are p parameters that need to be estimated. Substituting $k = 1, 2, \dots, p$ in equation (3), a set of p equations is obtained. These are called the *Yule-Walker equations*. Assume that the autocorrelations $\{\rho_1, \dots, \rho_p\}$ are known (or estimable from data). Then the p equations, derived from equation (3), may be used to obtain the p unknown parameters of the AR(p) model. If estimates of

2 Autocorrelation Function

the p autocorrelations are available, they may be inserted into the p Yule–Walker equations to obtain the Yule–Walker estimates of the parameters.

A major problem in building a time-series model is identifying the order of the model (analogously with the problem of determining the number of regressor variables in a multiple linear regression model). In autoregressive models, the identification problem is to determine p . Here, the *partial autocorrelation function* is useful. Suppose that we believe that the order of the model is m , and denote by ϕ_{mj} the j th coefficient in the Yule–Walker equations ($j = 1, 2, \dots, m$). Obviously, ϕ_{mm} will be the last coefficient. For the autocorrelation ρ_k we obtain, analogously with equation (3):

$$\begin{aligned} \rho_k &= \phi_{m1}\rho_{k-1} + \phi_{m2}\rho_{k-2} + \dots + \phi_{mm}\rho_{k-m}, \\ k &= 1, 2, \dots, m \end{aligned} \quad (4)$$

These Yule–Walker linear equations may be solved for the m coefficients $\{\phi_{mj}\}$ for successive values of m . The quantity ϕ_{mm} , regarded as a function of m , is called the *partial autocorrelation function*. Written in a matrix form, equation (4) may be written:

$$\begin{bmatrix} 1 & \rho_1 & \rho_2 & \dots & \rho_{m-1} \\ \rho_1 & 1 & \rho_1 & \dots & \rho_{m-2} \\ \cdot & & & & \\ \cdot & & & & \\ \cdot & & & & \\ \rho_{m-1} & \rho_{m-2} & \rho_{m-3} & \dots & 1 \end{bmatrix} \begin{bmatrix} \phi_{m1} \\ \phi_{m2} \\ \cdot \\ \cdot \\ \cdot \\ \phi_{mm} \end{bmatrix} = \begin{bmatrix} \rho_1 \\ \rho_2 \\ \cdot \\ \cdot \\ \cdot \\ \rho_m \end{bmatrix} \quad (5)$$

For example, from equation (5), one obtains by introducing successively $m = 1, 2$ the partial autocorrelations:

$$\phi_{11} = \rho_1; \quad \phi_{22} = \frac{\rho_2 - \rho_1^2}{1 - \rho_1^2} \quad (6)$$

A particular property of an autoregressive process of order p , AR(p), is that:

For $m \leq p$: ϕ_{mm} will be nonzero; For $m > p$: ϕ_{mm} will be zero.

Thus, calculating successively for $m = 1, 2, \dots, p, \dots$, one may find the correct order of an autoregressive model, given a sample of time-series values, by observing the values of the partial autocorrelation function. A sharp decline will be observed in the sample estimates of ϕ_{mm} for $m > p$.

Estimation

The Autocorrelation Function

The most satisfactory sample estimate, $\hat{\rho}_k$, of the autocorrelation, ρ_k , is (refer to [1], p. 31)

$$\hat{\rho}_k = \frac{\hat{\gamma}_k}{\hat{\gamma}_0} \quad (7)$$

where

$$\hat{\gamma}_k = \frac{1}{N} \sum_{t=1}^{N-k} (z_t - \bar{z})(z_{t+k} - \bar{z}), \quad k = 0, 1, 2, \dots, \quad (8)$$

is the sample estimate of the covariance, γ_k , $\bar{z}$ is the sample mean, and N is the **sample size**. Obviously, $\hat{\gamma}_0$ is the sample estimate of the variance.

If the theoretical shape of the autocorrelation function is known (like that for AR(1) introduced earlier), then estimates derived from equation (7) may be used to estimate the parameters of the assumed time-series model. Thus, for an AR(p) model, estimates of the autocorrelations may be inserted into the Yule–Walker equation (3) in order to derive estimates of the parameters $\{\phi_k\}$. For example, for AR(2), we obtain [1], p. 62:

$$\phi_1 = \frac{\rho_1(1 - \rho_2)}{1 - \rho_1^2}; \quad \phi_2 = \frac{\rho_2 - \rho_1^2}{1 - \rho_1^2} \quad (9)$$

The Partial Autocorrelation Function (for AR(p) Models)

Estimation of partial autocorrelations may be conducted by successively fitting autoregressive models (see **Time Series Analysis**) of an increasing order ($m = 1, 2, 3, \dots$), using **least squares**, and then picking up the estimates of the partial

autocorrelations $\{\hat{\phi}_{mm}\}$. These will comprise the last coefficients estimated from each model. Alternatively, inserting the estimated autocorrelations into equation (5) and solving for ϕ_{mm} would yield the required estimate of the partial autocorrelation for the $AR(m)$ model. As explained earlier, these successive partial autocorrelations ($m = 1, 2, \dots, p, \dots$) may help determine the order, p , of the $AR(p)$ model best suited for the time series.

HAIM SHORE

Bias of an Estimator

The difference between the expected value (*see **Expectation***) of an estimator and the population parameter it is supposed to estimate is called its

bias. Statistical bias is due to the specific algebraic form of an estimator. Selection bias arises because of inappropriate sampling. Measurement bias arises from a measurement system that is not appropriately calibrated.

Coefficient of Determination (R^2)

The coefficient of determination (usually denoted R^2) is a concept in *analysis of variance* and regression analysis. It is a measure of the proportion of explained *variance* present in the data. Hence, the higher the value of R^2 , the better the model describes the data. When data consists of values $y_1, \dots, y_n$ of a response variable and a model with predictor variables is applied to the data, then R^2 is defined as

$$R^2 = 1 - \frac{\sum_{i=1}^n (y_i - \hat{y}_i)^2}{\sum_{i=1}^n (y_i - \bar{y})^2} \quad (1)$$

where $\bar{y}$ denotes the average of the observations and $\hat{y}_i$ the prediction of y_i using the fitted model. In case there is no relation between the predictor variable(s) and the response variable, then $\bar{y}$ is the best “model” to explain the data. Hence, the terms $y_i - \bar{y}$ account for deviations in the worst case that there is no relation between the predictor variable(s) and the response variable. The range of values of R^2 depends on the type of model to be fitted; in standard cases like linear least-squares regression models they lie between 0 and 1.

In case of linear regression with only one predictor variable, R^2 equals the square of the *correlation* between the values of the predictor variable and the response variable. Several different formulas of R^2 are known, e.g., the formula

$$R_0^2 = 1 - \frac{\sum_{i=1}^n (y_i - \hat{y}_i)^2}{\sum_{i=1}^n y_i^2} \quad (2)$$

is used for linear regression models without intercept term. Using a form of R^2 that does not match the type of model may lead to wrong conclusion, since in general the different forms of R^2 are not equivalent (see [1] for an excellent overview).

Very low values of R^2 (<0.5) indicate a weak relation between the predictor variable(s) and the response variable, while moderately low values of R^2 (<0.8 and >0.5) indicate that the model is not adequate, e.g., terms are missing, or that there is substantial error variation (possibly caused by a large measurement spread). However, high values of R^2 do not necessarily imply that the model is adequate (see [1]). The major reason is that R^2 increases when models are enlarged, even when this is done with irrelevant terms. This effect is only partially taken away by using the adjusted form $R_{\text{adj}}^2 = 1 - \frac{n-1}{n-k-1} R^2$, when there are k predictor variables in a linear regression model (when there is no intercept, then the denominator should be $n - k$). A proper assessment of goodness of fit (see **Lack of Fit**) of a regression model should consist of a balanced judgment taking into account model assumptions, the explained variation by the model as well as the number of parameters in the model. This may be accomplished by analysis of the **residuals**, checking the number of significant effects, and performing a model significance test like the standard F -test in *analysis of variance* (which rigorously accounts for the *degrees of freedom* and hence, also incorporates the number of parameters).

ALESSANDRO DI BUCCHIANICO

Correlation

Correlation is a measure of the strength of the linear relationship between two random variables, which is independent of the measurement scale. Theoretically, the correlation between X and Y is defined as

$$\text{Cor}(X, Y) = \frac{\text{Cov}(X, Y)}{\sqrt{\text{Var}(X)\text{Var}(Y)}} \quad (1)$$

where $\text{Cov}(X, Y)$ denotes the *covariance* (see **Covariance**) of X and Y , and $\text{Var}(X)$ and $\text{Var}(Y)$ are the *variances* (see **Variance**) of X and Y . If X and Y are independent, $\text{Cor}(X, Y) = 0$ (although the converse is not necessarily true). If X and Y are linearly

related (positive or negative), the correlation equals 1 or -1 .

The most often used sample correlation coefficient is the Pearson product-moment correlation. For a set of N pairs of observations $(X_1, Y_1), \dots, (X_N, Y_N)$ it is defined as

$$r = \frac{1}{N-1} \sum_{i=1}^N \left(\frac{X_i - \bar{X}}{S_X} \right) \left(\frac{Y_i - \bar{Y}}{S_Y} \right) \quad (2)$$

with $\bar{X} = 1/N \sum_{i=1}^N X_i$; $\bar{Y} = 1/N \sum_{i=1}^N Y_i$; $S_X^2 = 1/N - 1 \sum_{i=1}^N (X_i - \bar{X})^2$; and $S_Y^2 = 1/N - 1 \sum_{i=1}^N (Y_i - \bar{Y})^2$. We have $-1 \leq r \leq 1$, with equality only if the data are distributed along a perfect line in a scatter plot. See also **Measures of Association**.

Covariance

$$\text{Cov}(X, Y) = E(X - EX)(Y - EY) \quad (1)$$

See also **Correlation**.

The covariance is a measure of the departure from independence of two random variables X and Y :

Covariate

In regression models (and more complex linear models, such as ANCOVA models) one models the relationship between the response (or dependent) variable and one or more explanatory (or

independent) variables. The term *covariate* is used in particular for explanatory variables whose effect is not the main interest in the study (but which are included in the analysis to prevent their influence from affecting the estimation of the parameters of interest). Covariates are also called *concomitant variables*.

Dependence

Dependence and Independence – Definition

Let A and B be two random events. The events A and B are said to be statistically dependent if, and only if (the two definitions below are equivalent):

$$P(A|B) \neq P(A); P(B|A) \neq P(B) \quad (1)$$

This definition implies that two random events are statistically independent if, and only if:

$$P(A \wedge B) = P(A)P(B) \quad (2)$$

The basic definition may be extended to a set of k random events. Analogously, k random variables $\{X_1, \dots, X_k\}$, are mutually statistically independent if, and only if, their joint density function is equal to the product of their individual marginal density functions:

$$\begin{aligned} f_{x_1, x_2, \dots, x_k}(x_1, x_2, \dots, x_k) \\ = f_{x_1}(x_1)f_{x_2}(x_2) \dots f_{x_k}(x_k) \end{aligned} \quad (3)$$

Relationship between Dependence and Correlation

If two random variables are independent they are necessarily uncorrelated (*see Correlation*). But the reverse is not true: two dependent variables can be uncorrelated. The only case when two random variables that are dependent are also necessarily correlated and *vice versa* (namely, two correlated random variables are also necessarily dependent) is when they have a joint **normal distribution**.

Expected Value of a Product of Functions of Independent Random Variables

From equation (3), a very important and useful result is the following. Let $g_i(X_i)$ be a function of a single random variable, X_i . If $\{X_1, \dots, X_k\}$ maintain equation (3), then:

$$E[\prod_{i=1}^k g_i(X_i)] = \prod_{i=1}^k E[g_i(X_i)] \quad (4)$$

For example ($k = 2$, X_1 and X_2 are independent): $E(X_1^m X_2^n) = E(X_1^m)E(X_2^n)$.

HAIM SHORE

Descriptive Statistics

Introduction

Having a collection of observations, one may wish to describe these data so that important information, implied from the sample, becomes clearly visible. One way to do this is to make a plot of the data, such as a histogram, a stem-and-leaf plot, or a box and whisker plot (refer to **Graphical Representation of Data**). When the data convey a relationship between two variables, a scatter plot is a common method. Finally, for a **time series**, the observations are often plotted along the time axis so that patterns may be easily discerned. Often, such plots are not enough, and one wishes to summarize the data by a set of descriptive numbers that convey the most important properties of the data. Descriptive statistics provide this summary information. The sample properties that the descriptive statistics reflect often correspond to properties of the statistical distribution, like central tendency, dispersion, and the asymmetry and “peakedness” of the distribution. Some of these statistics may be used to estimate the distribution’s parameters or moments (see **Moments**).

Descriptive Statistics

Measures of Central Tendency

Mean.

$$\bar{X} = w_1 X_1 + w_2 X_2 + \cdots + w_n X_n \quad (1)$$

where X_i is the i th sample observation, n is the **sample size**, and $\{w_i\}$ are weights so that $\sum_{i=1}^n w_i = 1$.

Median and Sample Quantiles. The median is defined as the 50th percentile (see **Quantiles**) of the sample. For symmetrically distributed data, the sample mean and the sample median will be close (the mean and the median are equal for symmetric distributions). The median is considered a robust indicator for central tendency.

In a more general context, assume that one has n observations, and these are arranged in ascending order: $\{X_{(1)}, X_{(2)}, \dots, X_{(n)}\}$ ($X_{(i)}$ is referred to as the *sample i th order statistic*). The sample p th quantile

(the quantile such that a proportion p of the sample observations are smaller or equal to it) is calculated by the following procedure (refer to [1]):

- Express $(n+1)p$ by $r+g$, where r is an integer and $0 \leq g \leq 1$. For example, for $n=20$, $p=0.75$: $(n+1)p = 21 \times 0.75 = 15.75$ ($r=15$, $g=0.75$).
- The sample p th quantile is:

$$Q_p = (1-g)X_{(r)} + gX_{(r+1)}, r < n \quad (2)$$

For $r=n$, $X_{(n+1)}$ is replaced by $X_{(n)}$. Equation (2) may be used to calculate the median and the interquartile range (“Interquartile Range”). The sample 100 p th *percentile* is equal to the sample p th *quantile*.

Mode. The mode is the value that appears with the highest frequency in the sample.

Measures of Dispersion

Standard Deviation (S) and Coefficient of Variation (CV).

$$S = \left[\left(\frac{1}{n-1} \right) \sum_{i=1}^n (X_i - \bar{X})^2 \right]^{1/2} \quad (3)$$

Note that while S^2 is an unbiased estimator of the population variance, S is not an unbiased estimator of the population standard deviation. An often used measure of *scaled* dispersion, based on the sample standard deviation, is the coefficient of variation:

$$CV = \frac{S}{|\bar{X}|} \quad (4)$$

Being scale less, CV allows comparison of dispersions for samples of observations measured on different scales.

Range.

$$R = X_{\max} - X_{\min} = X_{(n)} - X_{(1)} \quad (5)$$

where $X_{\max}$ and $X_{\min}$ are the largest and the smallest observations in the sample.

Interquartile Range.

$$IQR = Q_{0.75} - Q_{0.25} \quad (6)$$

2 Descriptive Statistics

where $Q_{0.25}$ and $Q_{0.75}$ are the first and the third *quartiles* (see **Quartiles**) (the 0.25 and 0.75 **quantiles**, respectively), calculated by equation (2). The interquartile range contains 50% of the sample data and it is considered a robust descriptor of the sample dispersion (like the median is for central tendency).

Skewness and Kurtosis

Other common descriptive statistics are the sample *skewness* (see **Skewness**) and *kurtosis* (see **Kurtosis**). These represent the shape parameters of a distribution, and they reflect the degree of asymmetry and flatness, respectively, of the distribution.

Exponentially Weighted Moving Average (EWMA)

For a time series (*see Time Series Analysis*) $X_1, \dots, X_n$, the **exponentially weighted moving average** at time t is defined recursively for $t = 1, \dots, n$ as

$$Y_t = (1 - \lambda)X_t + \lambda Y_{t-1}, \quad \text{for } 0 < \lambda < 1 \quad (1)$$

(where Y_0 is an initial value) and thus

$$Y_t = (1 - \lambda)X_t + (1 - \lambda)\lambda X_{t-1} + (1 - \lambda)\lambda^2 X_{t-2} + \dots \quad (2)$$

The weights decrease geometrically. The exponentially weighted moving average (EWMA) is a smoother often used in forecasting and process control. *See also Moving Averages.*

Homogeneity of Variances

Introduction

Many important statistical techniques view each observation as a deterministic expression plus random error (noise), and assume homogeneity of variance: the measurement errors have common variance σ^2 . Homogeneity of variance is also known as *homoscedasticity*. Lack of homoscedasticity is known as *heteroscedasticity* (see also **Heteroscedasticity**).

Effects of Heteroscedasticity

For some techniques, heteroscedasticity is fatal. As an example, consider the one-way analysis of variance (see **Analysis of Variance**). Here, observations are drawn from several groups, and the null hypothesis of equality of group means is tested via an F -test (see **Parametric Tests**). The one-way analysis variance model views an observation as the sum of the corresponding group mean and a random error. The F -test compares two estimators of the common variance σ^2 : the factor mean square and the residual mean square (see **Mean Square Error**). The former is always an unbiased estimator of σ^2 , whereas the latter is an unbiased estimator of σ^2 only if the null hypothesis holds. Homogeneity of variance is crucial for the F -test: if we allow the variance of the error to vary from group to group, rejection of the null hypothesis may be due to differences in group variances rather than differences in group means.

Heteroscedasticity may not only affect the validity of statistical tests, it may also have a negative effect on the coverage of **confidence intervals** and the accuracy of estimators.

Detecting Heteroscedasticity

Formal diagnostic tests and diagnostic plots for detecting heteroscedasticity have been proposed for analysis of variance, the linear regression model as well as the nonparametric regression model. The best known are Bartlett's test (see the section on Comparing Variances in **Parametric Tests**) and Levene's test. See also [1–4]. Box and Cox transformations [**Box and Cox Transformation**] may be used to reduce heteroscedasticity, see [5].

ALEX J. KONING

Hotelling's T^2

Hotelling's T^2 is the multivariate equivalent of Student's t -statistic, and measures the deviation of a sample average from a hypothesized mean or target vector τ . Working with p -dimensional data (typically assumed to have a multivariate **normal distribution**), one has n p -tuples $\mathbf{X}_1, \dots, \mathbf{X}_n$. With the

p -dimensional vector $\bar{\mathbf{X}}$ denoting the sample average, and $\mathbf{S}^{-1}$ denoting the inverse of the sample **covariance** matrix, Hotelling's T^2 statistic is

$$T^2 = n(\bar{\mathbf{X}} - \tau)' \mathbf{S}^{-1} (\bar{\mathbf{X}} - \tau) \quad (1)$$

In industrial statistics the statistic is used in multivariate control charts (*see* **Multivariate Control Charts Overview**). See also **Multivariate Analysis**.

Kurtosis

The kurtosis of a random variable X is related to the fourth *moment* (see **Moments**) of its distribution:

$$\gamma_2 = \frac{\mu_4}{\sigma^4} - 3 \quad (1)$$

where $\mu_4 = E(X - EX)^4$ and $\sigma^2 = E(X - EX)^2$. Distributions with high kurtosis are typically heavy tailed whereas distributions with low kurtosis are light tailed.

Lack of Fit

In parametric modeling one speaks of lack of fit if there is a systematic discrepancy between the predicted values and the observed values due to the chosen parametric model. Substantial lack of fit occurs, for example, if one approximates a curved relationship by a linear function, or if significant interaction terms are dropped from a model. In the design of experiments it is good practice to

include a few design points that enable the assessment of lack of fit, such as runs in the *center point* (see **Center Points**) of a two-level **factorial** design. If the design and the chosen model allow, the error **sum of squares** in the analysis is typically broken down into a pure error term (due to noise) and a lack-of-fit term (see **Analysis of Variance**).

Leverage

Leverage in Linear Regression Analysis

In regression analysis, leverage is a measure of the influence of a given observation on the regression line due to the location of the values of the independent variables. This may happen when an observation is taken at values of the independent variables far away from other observations. The common *least-squares estimation* method in linear regression analysis forces regression models to be close to observed values taken at remote values of the independent variables (see Figure 1). Hence, small changes in the measured response at remote observations may have a large effect on the coefficients of the regression model. It is important to detect such observations. For linear regression models of the form $Y = X\beta + \varepsilon$, the *least-squares* estimator can be written as $\hat{y} = Hy$, where the hat matrix H is given by $X(X^T X)^{-1} X^T$. The matrix elements h_{ij} of the hat matrix can be interpreted as the amount of influence of observation y_j on fitted value $\hat{y}_i$. As a rule of thumb, observations for which the corresponding diagonal element of the hat matrix exceeds $2p/n$ (where p is the number of terms in the regression model and n is the number of observations) are considered to be influential. This is a practical test, but it only works for observations taken at remote values of the independent variables. There exist other influence measures that quantify the effect of deleting individual observations that apply to all observations. Well-known examples include Cook's D , $DFFITS$, and $DFBETAS$. Let p be the number of terms in the linear regression model and denote the standardized *residuals* by r_i . Then one of the forms for Cook's D is given by $\frac{r_i^2}{p} \left(\frac{h_{ii}}{1-h_{ii}} \right)$. When Cook's D exceeds $4/n$, then the i th observation is considered to have caused a significant shift of the entire parameter vector β due to the i th observation. If one is interested in the shift of a single parameter β_j , then one may use $DFBETA_{j(i)}$ which is defined by $\frac{\hat{\beta}_j - \hat{\beta}_{j(i)}}{s_i \sqrt{c_{ii}}}$, where c_{ii} denotes the i th diagonal element of the matrix $(X^T X)^{-1}$ and $\hat{\beta}_{j(i)}$ is the estimate for β_j based on the data set without the

Figure 1 Leverage: the regression line is forced to be close to the remote observation

i th observation. $DFBETA_{j(i)}$ has a cutoff value of $2/\sqrt{n}$. The measure $DFFITS$ measures the difference between the model predictions for the i th observation based on the complete data set and those based on the data set without the i th observation. $DFFITS$ is defined as $\frac{h_{ii}}{1-h_{ii}} \frac{e_i}{s_{(i)} \sqrt{1-h_{ii}}}$, where e_i is the i th *residual* and $s_{(i)}$ denotes the *standard deviation* based on the data set without the i th observation. It has a cutoff value of $2\sqrt{p/n}$. Extensive information on these and other influence measures can be found in [1, 2]. The distance on which these measures are based are similar to those employed in **multivariate statistics**, in particular, the Mahalanobis distance.

Mean Square Error

In *analysis of variance* (see **Analysis of Variance**) the total **sum of squares** is divided into a sum of squares attributed to the factors, and a residual sum of squares (often called the *error sum of squares*). The residual sum of squares divided by the residual **degrees of freedom** is the mean square error (MSE). The square

root of the MSE is often used as an estimator of noise in the measurements. For example, in the simple linear regression analysis $y_i = a + bx_i + \epsilon_i$, $i = 1, \dots, n$, the MSE is given by

$$MSE = \frac{1}{n-2} \sum_{i=1}^n (y_i - \hat{y}_i)^2 \quad (1)$$

with $\hat{y}_i$ the least-squares fit for y_i .

Measures of Location

Measures of location are statistics that yield information on the point of gravity or the center of the data. A more formal description is a function of data that is equivariant under affine transformations, i.e., commutes with the group of transformations $x \rightarrow ax + b$. Common examples include the sample mean $\sum_{i=1}^n x_i/n$, the sample median (the middle value of the data after sorting from small to large in the case of an odd number of observations or the average of the two middle values in the case of an even number of observations), and the sample mode (the value that appears most frequently; this need not be a unique value). When data are normally distributed (*see* **Normal Distribution**), then the sample mean is the optimal estimator for the population mean in the sense that it is the unique unbiased estimator with minimal variance. A disadvantage of the mean is that it is not robust against *outliers*. Well-known alternatives that have a certain resistance against outliers include the median, the shorth (the sample mean of the shortest intervals containing at least half of the observations), *trimmed*

means (sample means when extreme order statistics have been removed), winsorized means (sample means when extreme order statistics have been set to an extreme order statistic), and the Hodges–Lehmann estimator (median of pairwise averages). Many of these sample statistics can be derived from general construction principles or techniques for estimators, like **Maximum Likelihood**, method of **moments**, M-estimators (extension of Maximum Likelihood), L-estimators (linear combinations of order statistics), or R-estimators (rank-based estimators). We refer to [1] for extensive details.

Maximum Likelihood; Normal Distribution; Outliers; Trimmed Mean.

ALESSANDRO DI BUCCHIANICO

Measures of Scale

Measures of scale are statistics that yield information on the spread of data. A more formal definition is that it is a function of data that changes with a multiplicative factor $|a|$ after applying an affine transformation $x \rightarrow ax + b$. The most well-known example is the standard deviation, which is the square root of the sample variance $\sum_{i=1}^n (x_i - \bar{x})^2 / (n - 1)$ (the sample *variance* is more tractable from a computational point of view, but has the drawback that it does not have the right unit when applied to physical data). A disadvantage of the standard deviation is that it is not robust against *outliers*. This is even more the case for the range (the difference of the largest and the smallest observation), which was a popular alternative to the standard deviation in the precomputer era. The range and the related average moving range (AMR) $\sum_{i=1}^{n-1} |x_{i+1} - x_i| / (n - 1)$ are often used in **quality control**, especially for **control charts** (see **Moving Range and R Charts**). Well-known alternatives that have a certain resistance against *outliers* include the interquartile range (distance between third and first *quartile*), the median

absolute deviation (MAD), which is the median of the absolute deviations from the median), and the length of the shorth (the shortest interval containing at least half of the data, see **Measures of Location**). Many of these sample statistics can be derived from general construction principles or techniques for estimators, like *Maximum Likelihood*, method of **moments**, M-estimators (extension of maximum likelihood), L-estimators (linear combinations of order statistics), or R-estimators (rank-based estimators). We refer to [1] for extensive details.

Monte Carlo Methods

Monte Carlo methods – definition and common uses

Monte Carlo methods refer to computer-intensive methods which are used to mimic *unknown* statistical distributions of *output* random variables, *via* generation of random numbers from *input* random variables with *known* distributions. Both input and output variables (random or deterministic) are tied together by a stochastic model. Application of **Monte Carlo** methods is conducted in the framework of **Monte Carlo simulation** (namely, simulation that is stochastic in some manner). Major areas of application of Monte Carlo methods include:

- Obtaining numerical solutions to certain mathematical problems which are too complicated to solve analytically (such as the calculation of algebraically intractable integrals *via* Monte Carlo integration).
- Finding optimal solutions for problems too complex to solve mathematically (like NP-complete problems) *via* optimum-search techniques (like simulated annealing and **genetic algorithms**).
- System simulation (like physical, biological, and financial systems) in order to study and predict their behavior under various stochastic scenarios.
- Simulating distributions of statistics with unknown distributions for statistical inference (**bootstrap** and jackknife methods).
- Inverse problems, where a large collection of possible models are pseudorandomly generated *via* Monte Carlo methods and the associated likelihood of model's properties are evaluated.

Some techniques employed in Monte Carlo simulation

A major effort in Monte Carlo simulation relates to generating random numbers from the specified distributions. There are several general methods for random number generation, like rejection methods or the simpler inversion method. The latter refers to the case where random numbers need to be generated from a distribution with a known inverse cumulative distribution function (cdf) (*see* **Cumulative Distribution Function (CDF)**). Since any cdf, expressed

as a function of its random variable, is uniformly distributed, introducing a set of numbers, sampled from the uniform distribution on the (0, 1) interval, into the *inverse* cdf would produce a set of random numbers that has the desired distribution. For example, for the inverse cdf of the exponential distribution with parameter λ :

$$x = F^{-1}(P) = -(1/\lambda)\exp(1 - P) \quad (1)$$

where $P = F(X \leq x)$, X is exponentially distributed with parameter λ . Since P is uniformly distributed, uniformly distributed random numbers introduced into equation (1) would produce exponentially distributed numbers. When the distribution does not have an explicit inverse, like the **normal distribution**, special methods have been devised to generate the required distribution (including approximations for the algebraically intractable inverse cdf). Simulation software packages nowadays have random number generators for most commonly used distributions. These methods actually generate *pseudorandom* numbers since deterministic methods are used for the generation of the random numbers.

A second major effort in application of Monte Carlo methods is variance reduction. Variance reduction techniques aim to generate simulation data with minimal variance in order to increase the precision of estimates derived from the simulated data. There are several available variance reducing techniques, like antithetic **resampling**, the method of control variates, indirect **estimation**, and others.

Monte Carlo methods in quality and reliability engineering

Monte Carlo methods are extensively employed in reliability engineering to compute reliability of systems with complex configurations, or systems with components that are not necessarily statistically independent. Another common application is to calculate algebraically intractable integrals that appear in reliability-related calculations. The effects of various policies of preventive maintenance or various warranty policies are also often examined *via* Monte Carlo methods. In quality engineering these methods are used to assess the impact of a product design change, examine the effect of process improvement, and to optimize operating conditions of a running process.

HAIM SHORE

Moving Averages

Introduction

A moving average is a time-dependent weighted average, which is repeatedly recalculated as further observations in a **time series** become available. The name derives from the fact that the average “moves” through the time series. As more observations are collected, they are added to the calculation of the average, and at the same time observations from the most distant past are deleted (or given smaller weights). There are two basic reasons to calculate a **moving average**:

- **Prediction**

A moving average performs *smoothing* of the various components that comprise the time series (like trend, seasonality, or randomness), so that predicting immediate-future values of these components, based on the appropriate moving average, is less affected by fluctuations that had occurred in these components in the past.

- **Adaptive control**

To provide predicted values for a monitored process variable that will reflect adaptation, in a controlled manner, of the forecasting method to changes that have recently occurred in the process. The predicted values, based on the moving average, may then serve as baseline to detect out-of-control states for the process (*see Exponentially Weighted Moving Average (EWMA)*).

Unlike time-series modeling, a moving average does not attempt to model the data. Rather it attempts

to smooth the data so that any *long-term* signal embedded in the observations becomes more visible.

The Standard Moving Average

This average, calculated to predict the observation at time t , and based on the most recent n observations (collected from time $t - n$ until $t - 1$), is the weighted average

$$\bar{X}_t = w_1 X_{t-1} + w_2 X_{t-2} + \cdots + w_n X_{t-n} \quad (1)$$

where the weights sum to 1: $\sum_{i=1}^n w_i = 1$. It is customary to assign smaller weights to more ancient data.

The Exponentially Weighted Moving Average

Alternatively, one could use the **exponentially weighted moving average**:

$$\bar{X}_t = \lambda X_t + (1 - \lambda) \bar{X}_{t-1} = \bar{X}_{t-1} + \lambda(X_t - \bar{X}_{t-1}), \quad 0 \leq \lambda \leq 1 \quad (2)$$

where $\bar{X}_0 = X_0$ (*see for further details Exponentially Weighted Moving Average (EWMA)*). A larger λ would provide better (quicker) adaptation to most recent fluctuations, and thus less smoothing of these fluctuations. It is easily shown that the average in equation (2) is in fact an exponentially-weighted average of all previous observations, where weights become smaller the older an observation is.

HAIM SHORE

Multi-Vari Chart

A Graphical Tool for the Discovery of Sources of Variation

The multi-vari chart is a graphical tool, mainly used in **Exploratory Data Analysis**, which provides a display of the behavior of a quality characteristic in the running process. Variance components and patterns in the data are easily recognized.

Seder [1] introduced the multi-vari chart and compares it with the $\bar{X}$ -bar, R control chart (*see Control Charts, Overview*). It presents an analysis of the variation in a process, differentiating among three main sources: intrapiece (the variation within a piece, batch, lot); interpiece (the additional variation between pieces); and temporal variation. Duncan [2] presents the multi-vari chart as a graphical tool for testing joint homogeneity of means and variance in a nested structure. Bhote [3] discusses the multi-vari chart as a tool useful for generating clues about factors that cause process variation.

To illustrate the multi-vari chart, we consider data from a tea packing process, where the weights of boxes filled with 20 tea bags are determined. During each of 11 days, five consecutive boxes were sampled from each of four packing machines. By Y_{ijk} , $i =$

$1, \dots, 11$; $j = 1, \dots, 4$; $k = 1, \dots, 5$, we denote the weight of the k th box from the j th machine on the i th day. Figure 1 shows the multi-vari chart made from these data. On its y axis, it has the scale of the measurements, grams in this case. On the x axis are the indices from the samples. From each machine sample, the minimum and the maximum weights are indicated by a solid box. For each sample, the two boxes are connected by a vertical line, representing the range of the machine sample. Within each day, the sample means of the four machine samples are connected by a line. Finally, the crosses indicate the day means.

Studying the chart in Figure 1, we see that the sample taken at the seventh day at the second machine, and the eighth day's samples of the first and second machines require a closer examination. Inspection of the corresponding individual weights learned that there are four boxes that have a weight under 76 g or above 84 g. Because there should be 20 tea bags in a box, and the nominal weight of a tea bag is 4 g, it is likely that in these four boxes there is either one tea bag missing, or one tea bag too many.

Besides such errors, the multi-vari chart gives information about variance components. Substantial spread among the crosses (the day means in Figure 1) is indicative for a significant variance component associated with time. Steep rises and drops in the

Figure 1 Multi-vari chart for weights of tea boxes

2 Multi-Vari Chart

lines connecting machine means within days shows substantial interpiece or stream-to-stream differences. Tall vertical bars within the machine samples indicate substantial intrapiece spread. Besides variance components, the multi-vari chart also shows trends and systematic patterns between machines and over time.

De Mast *et al.* [4] give a thorough discussion of the multi-vari chart and augment the tool with tests based on control limits. Equipped with these control limits, one could regard the multi-vari chart as an extension of the $\bar{X}$ -bar, R control chart, allowing for two factors instead of one. Another related tool is the analysis of means (ANOM) [5].

Nonparametric Tests

Introduction

Nonparametric tests are the counterparts to *parametric tests* (see **Parametric Tests**). Typically, parametric tests assume that the data are drawn from a distribution, which has a finite number of unknown parameters, often the **normal distribution** with unknown mean μ and σ^2 . In contrast, nonparametric tests do not rely on such rather restrictive distributional assumptions, and hence are also known as *distribution-free tests*.

The parameter space is the set of all possible values of the unknown parameters. In mathematical statistics, a statistical method is called *parametric* when the parameter space is finite dimensional, and *nonparametric* when the parameter space is infinite dimensional, such as the space of all possible distribution functions. To complicate matters, there are also semiparametric models in which the parameter vector consists of a finite-dimensional part and an infinite-dimensional part. For instance, if we assume that we are dealing with data from a distribution that is symmetric around some unknown median η , then we are in essence dealing with a semiparametric model, as the parameter vector consists of a finite-dimensional part η and an infinite-dimensional part, a distribution that is symmetric around zero. Below, we shall ignore the distinction between nonparametric and semiparametric methods.

Permutation Tests

Nonparametric tests have been around since the early days of statistical inference. Perhaps the oldest form of nonparametric test is the permutation test, see [1, 2]. If data have been obtained from experiments that involve **randomization**, then we may assess the statistical significance of a permutation test by recalculating the test statistic for every permutation of the data consistent with the randomization. Obviously, permutation tests are computer intensive, which has impeded practical use for a long time. Recently, there is renewed interest in permutation tests.

Rank Tests

The computational demands of a permutation test may be drastically reduced by replacing the observations with their (transformed) ranks before actually performing the test. The resulting test is called a *rank test*.

An illustrative example is the signed rank test, see [3]. This test assumes that n observations are drawn from a distribution that is symmetric around an unknown location θ . The signed rank test may also be applied to paired data.

The null hypothesis to be tested is $H_0 : \theta = \theta_0$. The test assigns ranks to the observations according to their distance to θ_0 . Therefore, the observation closest to θ_0 is assigned rank 1. The test statistic T is obtained by summing the ranks belonging to the observations smaller than θ_0 , and is asymptotically normal.

To assess statistical significance (see **Significance Level**), we recalculate this rank sum for every permutation of the data. For example, if $n = 4$, then under the null hypothesis there are 2^4 equally likely outcomes for the ranks assigned to the observations smaller than θ_0 see Table 1.

Thus, the test statistic T takes values 0, 1, 2, 8, 9, and 10 with probability $1/16$, and values 3, 4, 5, 6, and 7 with probability $1/8$.

It is known that the test statistic T has an approximately normal distribution for $n \geq 20$. Under the null hypothesis, the test statistic T has expected value $n(n+1)/4$ and variance $n(n+1)(2n+1)/24$, and hence approximate critical values of the standardized

Table 1 Derivation of the null distribution of the rank sum test statistic for $n = 4$. The rank sum test statistic is the sum of the ranks assigned to observations smaller than θ_0

Ranks assigned	Rank sum T	Ranks assigned	Rank sum T
–	0	2, 3	5
1	1	2, 4	6
2	2	1, 2, 3	6
3	3	3, 4	7
1, 2	3	1, 2, 4	7
4	4	1, 3, 4	8
1, 3	4	2, 3, 4	9
1, 4	5	1, 2, 3, 4	10

2 Nonparametric Tests

test statistic

$$\frac{T - \frac{n(n+1)}{4}}{\sqrt{\frac{n(n+1)(2n+1)}{24}}} \quad (1)$$

may be determined by means of the standard normal distribution for $n \geq 20$. For $n < 20$, tabulated critical values have to be used.

Another example is the two-sample rank sum test, see [3, 4]. It involves two independent samples. Suppose that the first sample has size n_1 and is drawn from a distribution with population median η_1 and that the second sample has size n_2 and is drawn from a distribution with population median η_2 , the null hypothesis to be tested is $H_0 : \eta_1 = \eta_2$.

The combined sample is ranked from the least to the greatest. The Wilcoxon rank sum test statistic W is the sum of the ranks assigned to the first sample. It is known that the test statistic W has an approximately normal distribution when both sample sizes n_1 and n_2 are larger than 10. Under the null hypothesis, the test statistic W has expected value $n_1(n_1 + n_2 + 1)/2$ and variance $n_1 n_2 (n_1 + n_2 + 1)/12$. Therefore, approximate critical values of the standardized test statistic

$$W - \frac{n_1(n_1 + n_2 + 1)}{2} \quad (2)$$

$$\sqrt{\frac{n_1 n_2 (n_1 + n_2 + 1)}{12}}$$

may be determined by means of the standard normal distribution for $n_1, n_2 \geq 10$. The Mann–Whitney test statistic U is related to W , and is, in fact, given by

$$U = W - \frac{n_1(n_1 + 1)}{2} \quad (3)$$

It follows that the Wilcoxon rank sum test and the Mann–Whitney test are equivalent.

A further example is the Kruskal–Wallis test, which compares the effects of $k > 2$ treatments. To each treatment, there belongs a sample, and these samples are independent. The Kruskal–Wallis test assumes that

$$X_{ij} = \eta + \tau_j + \epsilon_{ij} \quad (4)$$

where X_{ij} is the j th observation in the i th sample, η is an unknown constant, τ_j is the unknown effect

of treatment j , and the error variables, ϵ_{ij} 's, are a random sample from a distribution with median 0. The null hypothesis to be tested is

$$H_0 : \tau_1 = \tau_2 = \dots = \tau_k \quad (5)$$

Rank the combined sample from the least to the greatest, and let $\bar{R}_j$ denote the mean of the ranks assigned to sample j . The Kruskal–Wallis test statistic is defined as

$$H = \frac{12}{N(N+1)} \sum_{j=1}^k n_j (\bar{R}_j - \bar{\bar{R}})^2 \quad (6)$$

where n_j is the size of sample j , $N = n_1 + \dots + n_k$ is the size of the combined sample, and $\bar{\bar{R}} = (N+1)/2$ is the average rank in the combined sample. The null hypothesis is rejected for large values of H . Under the null hypothesis, H approximately follows a χ^2 distribution with $k-1$ **degrees of freedom** for $\min(n_1, \dots, n_k) \geq 5$.

Instead of rank sums $\sum R_i$, one may use sums of transformed ranks $\sum a(R_i)$. For instance, the two-sample Savage test employs the transformed ranks

$$a(R_i) = \sum_{j=N-R_i+1}^N 1/j \quad (7)$$

see [5].

Rank tests may be generalized so as to accommodate censored observations. Generalizations of the two-sample rank sum test and the Savage test are found in [6] and [7], respectively. The latter test is commonly known as the *logrank test* and is related to the Cox regression model.

For an extensive overview of rank tests, refer to [8, 9].

Resampling Methods

The advent of high-speed computing has had a beneficial effect on nonparametric statistics. As computation became fast and cheap, ideas that had been around for some time suddenly became applicable. In particular, this holds true for permutation tests and resampling methods, see [10].

Resampling methods are related to permutation tests. However, instead of permuting the data, subsamples are drawn. The most prominent resampling

method is the **bootstrap**, see [11]. In its simplest form, the bootstrap constructs bootstrap samples by sampling with replacement from the initial sample. Often, the bootstrap is used to construct confidence intervals. However, the bootstrap may also be used to obtain critical values for some test statistic.

Let $X_1, \dots, X_n$ be a sample drawn from P_θ , where θ is a (possibly infinite-dimensional) parameter that belongs to some parameter space. We intend using the test statistic $T_n = T_n(X_1, \dots, X_n)$ to test the null hypothesis $H_0 : \theta \in \Theta_0$ versus $H_1 : \theta \in \Theta \setminus \Theta_0$, where $\Theta_0 \subset \Theta$. Let $\hat{\theta} = \hat{\theta}(X_1, \dots, X_n)$ be a consistent estimator of θ under the null hypothesis, and let $T_n^* = T_n(X_1^*, \dots, X_n^*)$, where $X_1^*, \dots, X_n^*$ is a bootstrap sample drawn from $P_{\hat{\theta}}$. The conditional distribution of T_n^* given $X_1, \dots, X_n$ is the bootstrap estimate for the null distribution of T_n . **Quantiles** of the bootstrap null distribution may act as bootstrap critical values for T_n .

The error in the probability of a type I error is of smaller order for a bootstrap test than for the corresponding asymptotical theory test if and only if T_n is an asymptotic pivotal quantity, that is, the asymptotic null distribution of the test statistic T_n does not depend on θ , see [12]. Therefore, a bootstrap test should preferably be based on an asymptotic pivotal quantity.

For instance, let Θ be the collection of distributions on the real line whose first 10 **moments** are finite, and let $X_1, \dots, X_n$ be a random sample drawn from a distribution belonging to Θ . Let Θ_0 be the set of elements of Θ that have mean μ_0 . Then, the bootstrap samples should be resampled from $X_1^0, \dots, X_n^0$, where $X_i^0 = X_i + \mu_0 - \bar{X}_n$. That is, X_i^0 is obtained by shifting X_i over a distance $\mu_0 - \bar{X}_n$. Note that the mean of the shifted sample $X_1^0, \dots, X_n^0$ is equal to μ_0 , and hence the empirical distribution of $X_1^0, \dots, X_n^0$ belongs to Θ_0 . Moreover,

the bootstrap test may be based on the studentized statistic $T_n = \sqrt{n}(\bar{X}_n - \mu_0)/S_n$, which is an asymptotic pivotal quantity.

ALEX J. KONING

Normal Distribution

Introduction

This article describes the univariate normal distribution, with brief references also to the bivariate normal distribution and the multivariate normal. For each of these, there are brief historical remarks, and discussions of distributional properties, sampling distributions, and related applications.

The Univariate Normal Distribution

Historical Remarks

The univariate normal distribution is probably the most important distribution in classical statistical theory and methods. This distribution has a “bell-shaped” continuous *probability density function* (see **Probability Density Function (PDF)**). In the history of statistics, it was first discovered by the German mathematician Carl F. Gauss in the early nineteenth century while he was studying certain problems in physics and astronomy. As a result, this distribution is also known as the *Gaussian distribution*.

Distributional Properties

A continuous univariate random variable X is said to follow a normal distribution with parameters μ and σ^2 , if its probability density function $f(x)$ is of the form

$$f(x) = \left[\frac{1}{(2\pi)^{1/2}\sigma} \right] \exp \left[\frac{-(x - \mu)^2}{2\sigma^2} \right] \\ -\infty < x, \mu < \infty, \text{ and } \sigma > 0 \quad (1)$$

in symbols, $X \sim N(\mu, \sigma^2)$. It can be shown by elementary calculus that the mean and the variance of this distribution are μ and σ^2 , respectively.

A random variable Z is said to follow a *standard normal distribution* if $Z \sim N(0, 1)$. The distribution function of Z , $\Phi(z)$, is then given by

$$\Phi(z) = \int_{-\infty}^z \left[\frac{1}{(2\pi)^{1/2}} \right] \exp \left(\frac{-u^2}{2} \right) du \quad (2)$$

Since the function $\exp(-u^2/2)$ is symmetric about 0, $\Phi(z)$ satisfies $\Phi(z) = 1 - \Phi(-z)$ for all z . The $(1 - \alpha)$ th *quantile* (see **Quantiles**) (or $100(1 - \alpha)$ th percentile) of a standard normal distribution, often denoted z_α in most textbooks, is the quantity that satisfies $\Phi(z_\alpha) = 1 - \alpha$, $\alpha \in (0, 1)$. Since the function $\Phi(z)$ cannot be expressed in a closed form, tables for the numerical values of $\Phi(z)$ and z_α are needed. Such tables can be found in most statistics books.

The following theorem, which can be proved by calculus, shows how a normal distribution with mean μ and variance σ^2 is related to the standard normal distribution.

Theorem 1 If $X \sim N(\mu, \sigma^2)$, then the random variable $Z = (X - \mu)/\sigma$ is distributed according to the standard normal distribution.

As a simple application of Theorem 1, it follows that

Fact 1. If $X \sim N(\mu, \sigma^2)$, then,

1. $\Pr[a < X \leq b] = \Phi((b - \mu)/\sigma) - \Phi((a - \mu)/\sigma)$ for all $a < b$;
2. the $(1 - \alpha)$ th quantile of the distribution of X is $\mu + z_\alpha\sigma$.

Thus, tables for the standard normal distribution can be used for any univariate normal distribution.

More detailed distribution properties of the univariate normal distribution can be found in Patel and Read [1] and other related sources.

Sampling Distributions

The χ^2 distribution, Student's t distribution, and the F distribution (see **Probability Density Functions**), generally considered to be the cornerstones of classical statistical analysis, are closely related to the normal distribution. Specifically, let $X_1, X_2, \dots, X_N$ be a random sample of size N from an $N(\mu, \sigma^2)$ distribution; let

$$\bar{X} = \frac{1}{N} \sum_{i=1}^N X_i \quad \text{and} \\ S^2 = \frac{1}{N-1} \sum_i^N (X_i - \bar{X})^2 \quad (3)$$

2 Normal Distribution

denote the sample mean and the sample variance, respectively. Then,

1. $\bar{X}$ has an $N(\mu, \sigma^2/N)$ distribution and $(N-1)S^2/\sigma^2$ has a χ^2 distribution with $N-1$ **degrees of freedom**. Furthermore, $\bar{X}$ and S^2 are independent.
2. $t = N^{1/2}(\bar{X} - \mu)/S$ has a Student's t distribution with $N-1$ degrees of freedom, where $S = \sqrt{S^2}$ is the sample standard deviation.
3. t^2 has an F distribution with degrees of freedom $(1, N-1)$.

Another important sampling distribution result related to the normal distribution is a fundamental theorem in **probability theory**, called the *central limit theorem*.

Theorem 2 Let $X_1, X_2, \dots, X_N$ be a random sample of size N from any population with mean μ and finite variance σ^2 . Then, for every fixed z ,

$$\lim_{N \rightarrow \infty} \Pr\{N^{1/2}(\bar{X} - \mu)/\sigma \leq z\} = \Phi(z) \quad (4)$$

This theorem provides an approximation for the distribution of $\bar{X}$ when N is large. In most applications,

$$\Pr[a < \bar{X} \leq b] \doteq \Phi(N^{1/2}(b - \mu)/\sigma) - \Phi(N^{1/2}(a - \mu)/\sigma) \quad (5)$$

when $N \geq 30$.

Related Applications

In various applications of statistical inference problems – including *estimation* (see **Estimation**) of the parameters and *hypothesis testing* (see **Hypothesis Testing**) – the above sampling distribution results are applied. These include the following:

1. For inference on μ when σ^2 is known, the results for the distribution of $\bar{X}$ and Theorem 2 may be applied.
2. For inference on μ when σ^2 is unknown under the assumption of normality, Student's t distribution may be used.
3. When making statistical inference on σ^2 under the assumption of normality, the χ^2 distribution may be used.
4. The normal distribution may be applied for inference on the difference of two normal means

when their variances are known. Similarly, the Student's t distribution may be applied for the same purpose when the variances are unknown but equal; in the hypotheses-testing problem, this is known as the *two-sample t test* (see **Parametric Tests**).

5. The F distribution may be applied for testing the equality of $k \geq 2$ normal means when the variances are assumed to be equal but unknown. This method is known as the *one-way analysis of variance (ANOVA) method* (see **Analysis of Variance**). When $k = 2$, it reduces to the two-sample t test as a special case.
6. Other results related to Theorem 2 are useful in large-sample inference problems. For example, it is known that under regularity conditions the *maximum-likelihood* (see **Maximum Likelihood**) estimator has an asymptotically normal distribution, and that the asymptotic null distribution of $-2 \ln \lambda$ is χ^2 , where λ is the likelihood-ratio function in a likelihood-ratio test.

The Bivariate Normal Distribution

Historical Remarks

Studies of the bivariate normal distribution seem to begin in the middle of the nineteenth century, and moved forward dramatically when Galton published his work [2] on the applications of **correlation** analysis in genetics. As Karl Pearson noted in his 1920 *Biometrika* paper [3], “In 1885 Galton had completed the theory of bivariate normal correlation” but, because he “was very modest and throughout his life underrated his own mathematical powers, he did not at once write down the equation” of the bivariate normal density function. Consequently, it was Pearson himself who gave a definitive mathematical formulation of the bivariate normal distribution in his 1896 paper [4] on regression and heredity.

Distributional Properties

A two-dimensional random vector (X_1, X_2) is said to have a bivariate normal distribution if their joint density function $f(x_1, x_2)$ is of the form

$$f(x_1, x_2) = [2\pi\sigma_1\sigma_2(1 - \rho^2)^{1/2}]^{-1} \exp\left[-\frac{1}{2}Q_2(x_1, x_2; \boldsymbol{\mu}, \boldsymbol{\Sigma})\right], \quad -\infty < x_1, x_2 < \infty \quad (6)$$

where

$$Q_2(x_1, x_2; \boldsymbol{\mu}, \boldsymbol{\Sigma}) = (x_1 - \mu_1, x_2 - \mu_2) \boldsymbol{\Sigma}^{-1} \times \begin{pmatrix} x_1 - \mu_1 \\ x_2 - \mu_2 \end{pmatrix} \quad (7)$$

defines an ellipse centered at $(\mu_1, \mu_2) \equiv \boldsymbol{\mu}$ (which is the mean vector), the 2×2 matrix

$$\boldsymbol{\Sigma} = \begin{pmatrix} \sigma_1^2 & \rho\sigma_1\sigma_2 \\ \rho\sigma_1\sigma_2 & \sigma_2^2 \end{pmatrix} \quad (8)$$

is the **covariance** matrix, and $\rho \in (-1, 1)$ is the **correlation** (see **Correlation**) coefficient.

The marginal and conditional distributions of a bivariate normal random vector are univariate normal. For details, see Tong [5, Section 2.1].

Sampling Distributions and Related Applications

The sampling distribution results involve the distributions of the sample mean vector $\bar{\mathbf{X}}$, the sample covariance matrix $\mathbf{S}$, the independence property of $\bar{\mathbf{X}}$ and $\mathbf{S}$, and the distribution of the sample correlation coefficient. Those results may be applied for estimation and hypothesis testing purposes. For details, see Anderson [6, Section 2.3] and Tong [5, Sections 2.1 and 2.2].

The Multivariate Normal Distribution

Historical Remarks

The development of the multivariate normal distribution theory, which originated mainly from the studies of regression analysis and multiple and partial correlation analysis, was treated comprehensively for the first time by Edgeworth in his 1892 paper [7]. The development of the sampling distribution theory under the assumption of normality (such as Fisher's work on the distributions of sample correlation coefficients and *Hotelling's* T^2 distribution; see **Hotelling's** T^2) then followed.

Distributional Properties

An n -dimensional random vector $\mathbf{X} = (X_1, \dots, X_n)$ is said to follow a multivariate normal distribution with mean vector $\boldsymbol{\mu} = (\mu_1, \dots, \mu_n)$ and covariance

matrix $\boldsymbol{\Sigma}_{n \times n} = (\sigma_{ij})$, in symbols $\mathbf{X} \sim N_n(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, if its joint probability density function is of the form

$$f(\mathbf{x}) = [(2\pi)^{n/2} |\boldsymbol{\Sigma}|^{1/2}]^{-1} \exp \left[-\frac{1}{2} Q_n(\mathbf{x}; \boldsymbol{\mu}, \boldsymbol{\Sigma}) \right], \quad \mathbf{x} \in \mathbb{R}^n \quad (9)$$

where

$$Q_n(\mathbf{x}; \boldsymbol{\mu}, \boldsymbol{\Sigma}) = (\mathbf{x} - \boldsymbol{\mu}) \boldsymbol{\Sigma}^{-1} (\mathbf{x} - \boldsymbol{\mu})' \quad (10)$$

The marginal and conditional distributions of a multivariate normal random vector are also normal. For details, see Anderson [6, Sections 2.3, 2.4, and 2.5] and Tong [5, Section 3.3].

Sampling Distributions and Related Applications

The sampling distribution results also involve $\bar{\mathbf{X}}$, $\mathbf{S}$, and their independence property; in particular, the results are related to Hotelling's T^2 distribution and the Wishart distribution (generalizations of the Student's t distribution and χ^2 distribution, respectively). There also exist distributional results on the sample regression equations and various types of sample correlation coefficients. Such results have been found useful for the purposes of prediction and correlation analysis. For details on sampling distributions, see Anderson [6, Chapters 4, 5, and 7], Tong [5, Sections 3.4 and 3.5], and other related sources. For related applications in inference, a classical reference is Anderson [6].

Normality Tests

Introduction

In testing normality, one should distinguish between the simple null hypothesis (parameters μ and σ^2 known) and the composite null hypothesis (parameters μ and σ^2 unknown). The simple null hypothesis is of little practical value.

Under the composite null hypothesis, the unknown parameters μ and σ^2 should be estimated. By using plug-in estimators, we may readily extend tests developed for the simple null hypothesis to the composite null hypothesis. However, plugging in estimators has a complicating effect on the null distribution of the test statistic. This makes it difficult to determine critical values and/or *p values* (see **P Values**).

Distance Methods

Distance methods are based on measuring the distance between a parametric and a nonparametric estimator of some function describing the distribution, such as the cumulative distribution function, the cumulative hazard function, or the moment generating function. In testing normality, the estimated normal cumulative distribution function and the empirical distribution function are typically used.

The asymptotic distribution of the composite null hypothesis versions of the Kolmogorov, the Cramér–von Mises, or the Anderson–Darling tests cannot be captured by a mathematical expression, and hence we have to resort to tabulation. The composite null hypothesis version of the Kolmogorov test is generally known as the *Lilliefors test*; [1] tabulates the null distribution of the test statistic.

Skewness and Kurtosis Tests

Instead of measuring the distance between the empirical distribution function and the estimated cumulative normal probability function, we may focus on certain characteristics of the **normal distribution**, such as the higher **moments**. For instance, it is known that the *skewness* (see **Skewness**) and *kurtosis* (see **Kurtosis**) of any normal distribution are equal to 0 and 3, respectively, and which suggests the use of

the third and fourth sample *moments* (see **Moments**) for testing normality. These tests are referred to as *directional*, as they lack the omnibus property of the distance-based tests. In [2] percentage points for various tests derived from skewness and kurtosis are given.

In econometrics, the Jarque–Bera test, see [3], is commonly used to test normality. This test is also derived from skewness and kurtosis.

Shapiro–Wilk-Type Tests

The normal *probability plot* (see **Probability Plots**) is a popular technique for exploring normality, and is a plot of the observations *versus* their corresponding ideal values, the so-called normal scores. If the data follow a normal distribution, the normal probability plot should be approximately linear. This suggests that we may test normality by quantifying the degree of nonlinearity in the normal probability plot.

The first test along these lines is the Shapiro–Wilk test, see [4]. Unfortunately, this test is computationally demanding. In particular, the Shapiro–Wilk test requires the inversion of a certain $n \times n$ **covariance** matrix V , where n denotes the sample size. In [5] it is argued that for large sample sizes, the covariance matrix V may be replaced by the identity matrix. This yields the Shapiro–Francia test, a simplified version of the Shapiro–Wilk test, which may be used for sample sizes larger than 50. In [6] it is recognized that the Shapiro–Francia test statistic is in fact the squared normal probability plot **correlation**, that is, the squared correlation between the observations and their normal scores; moreover, critical values for the normality probability plot correlation are given; see Figure 1. The Ryan–Joiner test in Minitab, see [7], only differs from the Shapiro–Francia test in the way the normal scores are obtained.

The close relation to the normal probability plot is an attractive aspect of the Shapiro–Wilk-type tests.

Comparison

In [8] results of a comparative study of various normality tests are given. Their findings include the following:

- the Shapiro–Wilk test provides a generally superior omnibus measure of nonnormality;

2 Normality Tests

Figure 1 An application of the Shapiro –Francia test. The correlation between the observations 6, 1, –4, 8, –2, 5, 0 and their normal scores is 0.984. The corresponding critical value at the 5% **significance level** is 0.899 [see 6 Table 1]. As $0.984 > 0.899$, the normality hypothesis is not rejected

- the distance-based tests are typically very insensitive;
- a combination of both sample skewness and sample kurtosis usually provides a sensitive judgment, but even their combined performance is usually dominated by the Shapiro–Wilk test.

In [9], the superiority of the Shapiro–Wilk test is confirmed. However, it is pointed out that the findings in [8] are misleading with respect to the distance-based methods: the Cramér–von Mises and Anderson–Darling tests with plug-in estimators perform slightly worse than the Shapiro–Wilk test.

ALEX J. KONING

Observational Studies

An observational study is an empirical investigation that attempts to estimate the effects caused by a factor when it is not possible to perform an experiment. Whereas in an experiment, factor settings

are assigned to runs by the inquirer, in observational studies, the inquirer does not manipulate the factors, but merely records the values that they happen to have. Contrary to experimental data, observational data demonstrate **correlation** rather than causation (*see* **Causality**).

Outliers

Outliers are observations that stand apart from the majority of the observations. Outliers may be caused by reading or typing errors, contamination (data comes from more than one source), faults of the **measurement system**, or incidents in the process. It is important to detect outliers, because statistical analyses may be heavily affected (and even become invalid) when outliers are present. Basically, there are two ways to deal with outliers. One approach is to discard or reject outliers using tests of discordancy (preferably after additional checking of the circumstances under which they were obtained). Another approach is accommodation, i.e., to adjust analyses so that they become robust against possible outliers. The former approach comes down to deletion of the data point or replacement with the missing data value, while the latter approach involves the use of robust procedures such the median or the **trimmed mean** instead of the sample mean.

The box plot is a simple graphical tool to detect outliers. As a rule of thumb, observations that are more than 1.5 or 2 times the interquartile range (IQR, see **Quartiles**) away from the median of the data are marked in box plots as outliers by plotting them as crosses. Formal tests for outliers include the Dixon's tests and the Grubbs tests. Both tests assume normality (see **Normality Tests**). Dixon's test statistic for detecting one outlier on the right is given by $(x_{(n)} - x_{(n-1)}) / (x_{(n)} - x_{(1)})$, where $x_{(i)}$ denotes the i th order statistic, i.e., the i th smallest observation. Similar test statistics exist for one or two outliers on the left or on both sides. Thus $x_{(n)}$ is the largest observation and possibly an outlier. Critical

values of the Dixon's test must be looked up in a statistical table as there is no closed-form formula for them.

The Grubbs tests are based on a transformation of the maximum studentized value of the sample, i.e., the largest among the values $(x_i - \bar{x})/s$, where $\bar{x}$ denotes the sample mean and s the sample standard deviation. The Grubbs test statistic for detecting one outlier on the right is given by $(x_{(n)} - \bar{x})/s$, with critical value $(n-1)t_{n-2,\alpha/n} / \sqrt{n(n-2 + t_{n-2,\alpha/n}^2)}$ where $t_{n-2,\alpha/n}$ is the value such that a Student's t -distribution with $n-2$ **degrees of freedom** has probability α/n of exceeding it.

Caution should be exercised when using such tests, because they may behave poorly for other alternative hypotheses. For example, Dixon's test for one outlier on the right may have poor **power** when there are two outliers on the right. We refer to [1] for a comprehensive overview on this topic and to [2] for a shorter, practical guide.

Pareto Chart

Pareto Analysis

Pareto analysis is a problem-solving technique for prioritizing which root causes for a given problem should be handled first. The main idea behind the technique is the empirical observation that 80% of the problems come from 20% of the causes. This empirical observation was named by Juran [1] after the Italian econometrician Pareto (1848–1923), who made this observation during his studies of the distribution of wealth. The 80–20 rule has later been shown to apply in many other contexts. Pareto analysis is one of Ishikawa’s seven basic quality tools.

The Pareto chart is a bar chart where the root causes or categories are shown ordered from high importance or frequency to lower importance or frequency. Pareto analyses may only be performed on data collected in a stable situation, so no trends may be present. Depending on the context, causes may be weighted by frequency, costs, impact. If causes are aggregated into categories, then care must be taken to ascertain that categories allow fair comparisons.

An example adapted from [2] shows defects found in printed circuit boards. The bars indicate the frequency of the errors ordered from left (most frequent) to right (less frequent). As can be seen from the scale on the right-hand side of Figure 1, the three most frequent defects account for slightly over 80% of the defects.

Pooled Variance, Pooled Estimate

When estimators are based on more than one sample, then pooling is the name for obtaining an estimator for a characteristic of the combined samples by combining estimates based on the individual samples. The reason for doing this is that a pooled estimator is more accurate because it is based on more observations. The basic example is the pooled *variance* that appears in **confidence intervals** and tests for the difference of the mean of two samples from *normal distributions* with the same variance. In this case the sample *variance* of the combined sample may be a biased estimator (*see* **Bias of an Estimator**) of the common variance, because it is a measure of deviation from the overall mean (which may be different from the means of the individual samples). The correct way is to use the pooled variance $((n_1 - 1)S_1^2 + (n_2 - 1)S_2^2)/(n_1 + n_2 - 2)$, which is an unbiased estimator of the common *variance* of the two samples. Note that pooling means in this case is not a problem, since the pooled mean $((n_1 - 1)\bar{X}_1 + (n_2 - 1)\bar{X}_2)/(n_1 + n_2)$ equals

the overall mean of the combined sample. However, see [1] for a very readable, practical discussion whether to pool or not. More generally, estimators are pooled in *analysis of variance*.

In case one is not certain whether it is allowed to pool the data, statistical tests may be performed to decide whether to pool or not. Such estimators are known under the name sometimes-pool estimator (see [2, 3] for further details).

Power

The power of a *hypothesis test* (see **Hypothesis Testing**) is the probability that the null hypothesis H_0 is rejected when some other hypothesis H is true. Suppose the hypotheses are about a parameter θ , and suppose H_0 specifies $\theta = \theta_0$, then the power function is defined as $\beta(\theta) = P_\theta(H_0 \text{ rejected})$. The

significance level of the test is $\alpha = \beta(\theta_0)$. For $\theta \neq \theta_0$, $\beta(\theta)$ gives the probability that H_0 is correctly rejected given the effect size $\theta - \theta_0$.

Probability Density Function (PDF)

Probability density functions (PDFs) are mathematical formulas that provide information about how the values of random variables are distributed. For a discrete random variable X assuming values in a sample space Ω , the density is usually named the *frequency distribution*, defined as $p_X(x) = P(X = x)$, for each x in Ω . If X is a continuous random variable, its density function f_X determines the probability that X is in an interval $[a, b]$,

namely,

$$P(a \leq X \leq b) = \int_a^b f_X(x) \, dx \quad (1)$$

In particular, the **PDF** determines the probability that X is smaller than x , namely, $F_X(x) = P(X \leq x) = \int_{-\infty}^x f_X(x) \, dx$. The function F_X is called the *(cumulative) distribution function of X* (see **Cumulative Distribution Function (CDF)**). The best-known density function is the Gauss curve, which defines the **normal distribution**. (See **Probability Density Functions**.)

Statistical Methods for Counts, Rates, and Proportions

Introduction

Counting, or enumerating, is one of the most basic arithmetic operations. You may count the number

1. of specified “events” occurring in time, space, or volume, like customers arriving at a service counter, flaws on woven fabric, bacteria in a suspension, or events occurring on a discrete item, like stains on a painted door;
2. of discrete items (sample units) possessing one of a specified set of exclusive and exhaustive categories, like pass/fail, or “never”, “rarely”, “frequently”.

In both cases the result is integer valued. In the first case it is common practice to report the number of events or the size-adjusted *rate* of occurrences. In the latter case, the integer-valued *frequency* of occurrence of the category is reported. When the totality of units being investigated is known, the *proportion* of units of the category may also be reported.

Basic Sampling and Distribution Models

Counts of Events. When the events are randomly dispersed in time or space, the distribution of the counts in 1 may be modeled by a *Poisson distribution* with a mean value that is proportional to the size (time span, length, area, or volume) of the observational unit (see **Poisson Processes**). The constant of proportionality is termed the *rate of occurrence*, or *incidence*.

Frequencies of Occurrence. When the classification of the individual items are independent of each other, with a constant probability of belonging to a specific class, then the *multinomial distribution* will model the frequencies effectively. When there are only two classes, the distribution is the *binomial* distribution. The sample *proportion* of observations

belonging to the category in question is an unbiased estimator of the probability.

The binomial and Poisson distributions are one-parameter distributions belonging to the so-called exponential families of distributions. The distributions are skewed with a variance that depends on the mean value. The **skewness** is less pronounced for large values of the mean. When the assumption of independence is violated, this may give rise to *overdispersion*, see below.

Transformations. Traditionally various transformations have been used to achieve approximate normality and **homoscedasticity** for count data such that classical statistical methods could be used. Thus, the *arcsine* was used for observed proportions, and for Poisson counts *square root* is used to achieve homoscedasticity, or $X^{2/3}$ for normality.

However, with more computing power available, more adequate analytical tools have been developed. Instead of transforming the data, contemporary tools respect the distributional shape of the observations and analyze linear models for some transformation of the mean value. The most prominent, the log-linear models for Poisson counts and the logit models for binomial proportions, will be introduced below.

Bayesian Inference

As the likelihood function corresponding to Poisson data is proportional to the **probability density function** of a *gamma distribution*, it follows that the natural conjugate prior distribution for Poisson data is a gamma distribution, and hence, the posterior distribution is again a gamma distribution.

A similar argument shows that the natural conjugate prior distribution for binomial and multinomial data is a *beta* and a multivariate beta distribution, respectively.

Contingency Tables

When events are counted, and classified by two or more categorical variables, the counts are often presented in tables of counts, each variable determining a “dimension” of the table. Similar presentations of frequencies are used when sample units are classified

2 Statistical Methods for Counts, Rates, and Proportions

by two or more categorical variables. Such a table is often referred to as a *contingency table*.

Two-Dimensional Tables

When there are only two dimensions in the table, a hypothesis of no association between the two categories may be formulated as a test for independence, or a test of homogeneity depending on the sampling method being used. In either case, the hypotheses is tested by Pearson's χ^2 test. For a 2×2 table Fisher's exact test is used (*see Parametric Tests*).

Log-Linear Models for Multiway Tables

The so-called log-linear models for multiway tables provide a versatile framework for analyzing association in multidimensional contingency tables. The models are appropriate for counts under unrestricted Poisson sampling and for frequencies under multinomial sampling. The idea is to formulate a *linear model* for the logarithm to the expected counts in individual cells. For a two-dimensional table, the log-linear model is

$$\ln(\lambda_{ij}) = \mu + \alpha_i + \beta_j + \gamma_{ij} \quad (1)$$

with suitable linear restrictions on the parameters.

A hypothesis of no association between the classifying variables is formulated in terms of the *interaction* term γ_{ij} as $H_0 : \gamma_{ij} = 0$.

For multidimensional tables a set of hierarchical (nested) models is formulated, each model spanned by a corresponding set of *sufficient marginals*. The approximate χ^2 distribution of the likelihood-ratio test statistic is utilized to reduce the model by successively removing higher-order interaction terms in analogy with **ANOVA** models for normally distributed observations (*see Analysis of Variance*).

Log-linear interaction models provide the most general terms for relationships among variables. However, the variables investigated by log-linear models are all treated as response variables, and no distinction is made between independent and dependent variables.

Logit Models, Odds

Modeling effects of explanatory variables on the response may be more important than modeling relationships between all variables. A subset of the log-linear models, the so-called logit models for the response variable serves this purpose.

Consider an $r \times c$ **factorial** experiment with a binary response, and let p_{ij} denote the probability of "success" in experiment (i, j) .

The *logit* transformation of a probability, p , is the logarithm to the corresponding *odds*

$$\eta(p) = \ln\left(\frac{p}{1-p}\right) \quad (2)$$

In analogy with equation (1) we now introduce the linear decomposition of the logit η_{ij}

$$\eta_{ij} = \eta(p_{ij}) = \mu + \alpha_i + \beta_j + \gamma_{ij} \quad (3)$$

with suitable linear restrictions on the parameters. The term γ_{ij} is called the *interaction term* in this linear logit model.

When the response is modeled by a multinomial distribution, a generalization of the logit approach may be utilized, see [1].

Graphical Models

The more dimensions a contingency table has, the greater the need for structuring the table in an operational, and interpretable manner. Complex stochastic models can often be constructed by combining simpler models through conditioning. This principle is utilized in the *graphical models*.

Graphical models are log-linear interaction models for contingency tables that can be represented by a simple undirected graph with as many nodes as the table has dimensions, and where the edges between the nodes represent conditional dependencies. It is a particular property for graphical models that they can be given an interpretation in terms of conditional independence in the sense that they allow for a factorization of the joint probability into a product of conditional distributions. The interpretation can be read directly off the graph in the form of a Markov property.

Graphical models with undirected edges are generally called *Markov random fields*, or *Markov networks*. See [2] for an introduction to graphical models. A more advanced text is [3].

Paired Samples. A particular situation arises when the observations are *paired*. This will typically be the case in before and after studies, or when two treatments are applied to each experimental unit. In these cases it is often appropriate to investigate a hypothesis of *marginal symmetry*. When the response is binary, the test reduces to a comparison of the off-diagonal terms with a binomial distribution with $p = 0.5$. The test is often referred to as *McNemar's test*.

Models for paired samples are also used for assessment of agreement between raters. Various metrics have been suggested to quantify agreement, see [4].

Correspondence Analysis

Correspondence analysis is a descriptive/exploratory technique designed to analyze simple two-way and multiway tables containing some measure of correspondence between the rows and columns. The results provide information which is similar in nature to those produced by factor analysis techniques, and they allow one to explore the structure of categorical variables included in the table, see [5] and [6].

Generalized Linear Models

The log-linear models and logit models considered above are special cases of the so-called **generalized linear models**. This class of models extends the *general linear model* for normally distributed variables to models for the mean-value structure for distributions belonging to an exponential family, like Poisson, binomial, or multinomial distributions.

The fundamental idea underlying these models is that instead of formulating linear models for the mean value itself, linear models are formulated for a function of the mean value, the *link function*. Hypotheses are tested by likelihood-ratio tests thereby taking the distributional properties of the observations into consideration. The contribution to the likelihood-ratio test statistic from an observation y_i , and the value, $\hat{\mu}_i$, estimated under the model is called the *deviance*, $d(y_i; \hat{\mu}_i)$. Thus, the deviance is a measure of how well an estimated model fits the observations in terms of log likelihood.

For the binomial distribution with **sample size** n , the deviance is

$$d(y; \hat{p}) = 2n \left\{ y \ln \left(\frac{y}{\hat{p}} \right) + (1 - y) \ln \left(\frac{(1 - y)}{(1 - \hat{p})} \right) \right\} \quad (4)$$

with y denoting the observed proportion. The deviance for Poisson data is

$$d(y; \hat{\lambda}) = 2 \left\{ y \ln \left(\frac{y}{\hat{\lambda}} \right) - (y - \hat{\lambda}) \right\} \quad (5)$$

The *residual deviance* is the sum of the individual terms $d(y_i; \hat{\mu}_i)$. The null distribution of the residual deviance is a χ^2 distribution. When a set of hypotheses is *nested* within each other, the residual deviance may be *partitioned* into contributions from each level just like the partitioning of the total **sum of squares** in an ANOVA context.

The *canonical link* is the function that transforms the mean value into the *canonical parameter* for the exponential family. For the Poisson distribution, the canonical link is the logarithm, and for the binomial distribution it is the logit. Linear models for the canonical link allow simple sufficient statistics for the parameters in the model.

We observe that the log-linear models for Poisson data, and the logit models for binomial data above correspond to modeling the canonical parameter by linear models in the explanatory variables.

Also, it should be noted that other link functions than the canonical link may be used. Thyregod and Spliid [7] give an example of an assembly situation where the logarithmic link provides a better, and more meaningful fit, for binomially distributed data.

An introduction to generalized linear models is given in [8] and [9], see also [10]. For applications in quality-improvement experiments, see [11].

More advanced statistical software has options for analysis of generalized linear models under various link functions.

Regression Models

Generalized linear models with continuous explanatory variables are sometimes referred to as *regression models*.

4 Statistical Methods for Counts, Rates, and Proportions

Poisson Regression

For Poisson data, the canonical link is the *logarithm*, and the log-linear regression model has the form

$$\ln(\lambda_i) = \alpha + \beta x_i \quad (6)$$

corresponding to

$$\lambda_i = \exp(\alpha + \beta x_i) \quad (7)$$

This model is often called *Poisson regression* model. Sometimes, when an *exposure* variable, t_i is present, the log exposure enters as an *offset* variable,

$$\ln(\lambda_i) - \ln(t_i) = \alpha + \beta x_i \quad (8)$$

Logistic Regression

For binomial data, the canonical link is the *logit*, and the linear model for the logit is

$$\ln\left(\frac{p_i}{1 - p_i}\right) = \alpha + \beta x_i \quad (9)$$

corresponding to the expression

$$p_i = \frac{\exp(\alpha + \beta x_i)}{1 + \exp(\alpha + \beta x_i)} \quad (10)$$

for the response probability. The function (10) is the *logistic function*, and hence the model is termed *logistic regression*.

The logistic regression is used to describe *dose-response* relationships when the response is binary. The model may be extended to cover multinomial response distribution, including models for *ordered categorical response*, see [1].

Dedicated statistical software often allows for other choices of link functions for regression models for binary responses. An example is the *complementary log-log* link

$$\ln\{-\ln[1 - p(x)]\} = \alpha + \beta x \quad (11)$$

corresponding to the dose-response function

$$p(x) = 1 - \exp[-\exp(\alpha + \beta x)] \quad (12)$$

The function grows slower away from 0, and approaches 1 faster than the logistic function.

Compound Models, Overdispersion

When there is greater variation in data than predicted by the sampling model, we speak of *overdispersion*.

Often for count data, several events are recorded on the same unit, such that the events are interdependent. This might result in overdispersion. Lee and Nelder [12] discuss the two ways of modeling overdispersion, either by introducing a constant factor, a *dispersion parameter* to the variance, or by using a *hierarchical model* where the mean of the counts is itself a random variable with a specified distribution.

In the hierarchical generalized linear models, the mixing distribution is chosen as the *natural conjugate* to the sampling distribution, see [13]. For Poisson data one would use a gamma distribution as compounding distribution, and the resulting marginal distribution would then be a *negative binomial* distribution. For binomial data, a beta distribution would be used, resulting in the so-called beta-binomial distribution of the counts.

Another common possibility is to use a normal compounding distribution for the canonical parameter (i.e., for the logit (binomial), and for $\ln(\lambda)$ in the Poisson case). This approach is used in the so-called generalized linear mixed models.

POUL THYREGOD

***P* Values**

A *P* value is frequently used to report the result of a *hypothesis test* (see **Hypothesis Testing**). A *P* value is defined as the probability, calculated under the null hypothesis, of obtaining a test result as extreme as that observed in the sample. Let the null hypothesis H_0 state that $\theta = \theta_0$, and let T be

a sample statistic, then $P = P_{\theta_0}(T \geq t)$, or $P = P_{\theta_0}(T \leq t)$, or $P = P_{\theta_0}(|T| \geq t)$ (depending on the direction specified by the alternative hypothesis). In the classical approach, one rejects H_0 if the *P* value is smaller than the desired *significance level* (see **Significance Level**) α of the test. Common choices for the significance level are 0.1, 0.05, and 0.01. See also **Power**.

Quartiles

For a continuous variable X , with distribution function F_X , the first, second, and third quartiles are $Q_1 = F^{-1}(0.25)$, $Q_2 = F^{-1}(0.50)$, and $Q_3 = F^{-1}(0.75)$

(that is, the values below which X will be with 25%, 50%, or 75% probability respectively). Note that the second quartile is equal to the median. *See also* **Quantiles**.

Residuals

Residuals could be said to be the difference between the observed values and the fitted values. In the context of linear models $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$, the ordinary

residuals are defined as $\mathbf{e} = \mathbf{Y} - \mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Y}$. Other types of residuals are standardized (or studentized) residuals and predicted residuals. Residuals are used for checking model assumptions and detecting **outliers**.

Runs, Runs Tests

A *run* is an uninterrupted sequence of observations all of which satisfy a certain criterion. For example, the sequence 00011010111 has a run of three 0's, then a run of two 1's, and so on. Similarly, we can speak of a run above average, a run below average, a "run up", and a "run down". In the sequence 5, 4, 6, 8, 10, 12, 11 there is a run up of length 4 since there are four increases in a row.

There are tests for randomness based on runs, and in particular in **quality control** runs have long been used as a criterion to detect when a process is out of control. Deming [1] suggested that a run up (or down) of length above six is indicative of a drift in the process. This and other runs tests (or "runs rules") are often used in Shewhart *control charts* (see **Control Charts, Overview**), in particular because the standard Shewhart chart is rather insensitive to small shifts. Nelson [2] lists eight tests for special causes, seven of which are based on runs. These tests are applicable for $\bar{X}$ and X (individuals) charts. They are often referred to as the *Western Electric rules*, as they were given in the company's 1956 *Statistical Quality Control Handbook*.

1. nine points in a row on the same side of the average,
2. six points in a row steadily increasing or decreasing (that is, a run up or a run down of length five),
3. fourteen points in a row alternating up and down,
4. two out of three points in a row more than two times the standard deviation from the average (on the same side),
5. four out of five points in a row more than the standard deviation from the average (on the same side),

6. fifteen points in a row within one time the standard deviation from the average (on either side),
7. eight points in a row more than the standard deviation from the average (on either side).

The run-length distributions of these tests are given (for a range of scenarios) in Champ and Woodall [3, 4], Palm [5], Walker *et al.* [6], and Shmueli and Cohen [7].

JEROEN DE MAST

Sample-Size Determination

Introduction

The objective of most inquiries is to collect data that may be turned into useful information for decision making. In a deterministic world, a single observation would most often suffice to provide the required information. For example, to determine the velocity of an object moving at a constant speed, a single observation of the distance traveled over a certain time would provide the required value of speed. Most often, however, the object of inquiry behaves randomly. This randomness might be captured by a statistical distribution (with constant parameters). Most often this distribution is unknown to us. Therefore, the conclusions derived from the data would frequently be associated with uncertainty. This uncertainty needs to be quantified so that a proper sample size be determined, in advance, which guarantees that uncertainty in the conclusions does not exceed prespecified thresholds. For example, a sample size may be required that would ensure a sample estimate of the proportion of rejects in the process that does not deviate more than 10% from the correct value, with confidence of at least 99%.

Occasionally, in addition to an element of randomness, the studied process itself may not be stable. For example, its mean may not be constant. In such cases, a relational model needs to be formulated, which will capture the observed systematic variation. Since the latter is often “clouded” with random variation (unlike the speed example given earlier), the ability to build a reliable model is often dependent on the amount of data collected. Again, sample size becomes a critical element that would determine the quality of the conclusions reached.

Finally, conclusions derived from observations may themselves be associated with costs that one wishes to minimize. For example, in **statistical process control** (SPC), not detecting lack of control, due to too small a sample size, may incur costs that one wishes to avoid. Formulating a model that comprises all costs associated with the sampling

process may be helpful in determining an optimal sample size that minimizes the expected total cost.

In this article, we address four common scenarios where a sample size needs to be determined: **hypothesis testing** (“Sample-Size Determination in Hypothesis Testing”), parameter **estimation** (“Sample-Size Determination in Parameter Estimation”), relational modeling (“Sample-Size Determination in Relational Modeling”), and optimal sampling planning (“Optimized Sample-Size Determination”).

Sample-Size Determination in Hypothesis Testing

In hypothesis testing (*see* **Hypothesis Testing**), there are two mutually exclusive claims about the true “state of nature”. These competing claims are described by the null hypothesis, which embodies the current state of our knowledge, and the alternative hypothesis, which reflects the claim that one wishes to test. Since the randomness in the data collected may lead to the adoption of a wrong hypothesis, the objective of sample-size determination is to guarantee that the probabilities to err do not exceed prespecified maximal values. The latter are denoted by α and β , respectively, for errors of the first and the second types. Quite often, the calculation of these probabilities to determine an appropriate sample size requires knowledge of certain parameters of the assumed data-generating distribution. Therefore, a preliminary small sample of observations is occasionally needed to provide initial estimates of the unknown parameters (most often those associated with the variance). The following numerical example demonstrates this.

Numerical Example

A certain improvement effort is scheduled for a chemical process, aimed to maximize its daily yield. A designed experiment is planned, according to which two samples of daily yields will be collected. One sample would be taken from the presently running process, and another would be taken after the implementation of an improvement effort. It is assumed that the variance of daily yield does not change as a result of the process of improvement. The two samples are to be of equal size, and it is desired

2 Sample-Size Determination

that testing the effectiveness of the improvement effort will guarantee maximum error probabilities of $\alpha = 1\%$, $\beta = 0.5\%$. Identification of an increase in yield of 10% (or more) is desired (smaller increase is regarded as inconsequential).

The required sample size can be determined as follows. Let μ_1 and μ_2 be the means of the process's yield before and after the improvement. It is required that the test has **power** of at least $1 - \beta = 0.995$ to identify an increase in yield of at least 10%. The two hypotheses are as follows:

$$H_0 : \mu_1 = \mu_2; H_1 : \mu_2 - \mu_1 \geq 0.10\mu_1 \quad (1)$$

Assume that the standard deviation of the daily yield, σ , is known, and that the sample average can be considered normally distributed. Under H_0 , the critical value for the sample average, above which H_0 will be rejected, is

$$\bar{X}_{cr} = \mu_1 + \frac{\sigma}{\sqrt{n}} Z_{1-\alpha} \quad (2)$$

where Z_p is the p th quantile of the standard **normal distribution** (100p% of the distribution does not exceed this value). Similarly, under H_1 :

$$\bar{X}_{cr} = 1.1\mu_1 + \frac{\sigma}{\sqrt{n}} Z_\beta \quad (3)$$

From these two equations, the required sample size is given by:

$$n = \left[\frac{\sigma(Z_{1-\alpha} - Z_\beta)}{0.1\mu_1} \right]^2 \quad (4)$$

Note, that equation (4) requires knowledge of σ . If the latter was unknown, a preliminary study would be needed that would provide the required sample estimate.

Sample-Size Determination in Parameter Estimation

In parameter estimation (*see Estimation*), a point estimate is derived from the data, which has some desirable characteristics (like unbiasedness, consistency, or minimum variance). In addition, an associated **confidence interval** (*see Confidence Intervals*) is constructed, which defines, with a prespecified confidence of $1 - \alpha$, an interval around the estimate, where the true value of the parameter is likely to be.

Specifying the desirable precision of the point estimate (the width of the confidence interval) and the required confidence level ($1 - \alpha$), the needed sample size is easily calculated from the distribution of the sample estimate.

Numerical Example

An estimate of the variance of the lifetime of a certain electronic component is required for **reliability analysis**. The following variance estimate, based on a sample of lifetime observations of n items, is used:

$$\hat{\sigma}^2 = \frac{1}{n-1} \sum_{i=1}^n (X_i - \bar{X})^2 \quad (5)$$

where $\bar{X}$ is the sample mean.

We determine a sample size n such that the upper limit (UL) of the confidence interval is no more than 25% larger than the lower limit (LL), while $\alpha = 10\%$. Assume that lifetimes may be considered as approximately normally distributed. It is known that $\hat{\chi}^2 = (n-1) \frac{\hat{\sigma}^2}{\sigma^2}$ is χ^2 distributed with $n-1$ **degrees of freedom** (σ^2 is the unknown true lifetime variance). Therefore a confidence interval may be defined by

$$LL = \frac{(n-1)\hat{\sigma}^2}{\chi_{1-\alpha/2}^2(n-1)} < \sigma^2 < \frac{(n-1)\hat{\sigma}^2}{\chi_{\alpha/2}^2(n-1)} = UL \quad (6)$$

where $\chi_p^2(n-1)$ is the p th quantile of a χ^2 distribution with $n-1$ degrees of freedom. It is required that

$$\frac{UL}{LL} = 1.25 = \frac{\chi_{1-\alpha/2}^2(n-1)}{\chi_{\alpha/2}^2(n-1)} \quad (7)$$

A simple search with some available software yields $n = 436$ (for $\alpha = 0.10$).

Sample-Size Determination in Relational Modeling

Relational modeling refers here to empirical modeling *via* multiple linear regression. The issue of sample size needed to obtain a reliable linear regression model is seldom addressed extensively in the literature (refer, for example, to [1, 2]), probably due

to the diversity of relevant considerations that may be involved. We expound some of these considerations.

A first consideration is whether the observations are collected in a designed experiment or in an observational study (see **Observational Studies**). In the former case, design optimality may affect to a large extent the amount of data required. An **optimal design** reduces the required sample size. For example, if the design aspires to reduce the variance of the required estimate (derived from the model), then design optimality would mean a reduced sample size. In the latter case (observational studies), there are far less opportunities to reduce the required sample size by the sampling procedure and the design of the **data collection** process. This implies that we can only *calculate* the required sample size, dependent on our objective.

In a more general perspective, sample-size determination in empirical modeling (like linear regression) depends on the modeling objective. Two major considerations, related to the quality of the model, are goodness of fit and stability. One may overfit the model, which implies that too many terms are included in the model relative to the available sample size, or one may underfit the model (underuse of the available information). In both cases, the model may not appropriately reflect the information provided by the available sample and either the model needs to be changed, or a larger sample size is required (when overfitting). A good indicator for proper model fitting is the AIC statistic (or the corrected AIC_c), which one wishes to minimize (for example, when several alternative models are examined). Good sources to learn of this consideration are [3, 4].

A second consideration is the model's stability. If a fitted model proves to be of low stability, a larger sample size is required to obtain satisfactory accuracy for the model parameters' estimates. The stability of a model may be learned from the relative widths of the confidence intervals associated with the parameters' estimates (the width of the confidence interval, divided by the parameter's point estimate, should not be larger than 1, and preferably much smaller than that). Another good indicator for stability is prediction error **sum of squares** (PRESS; refer to [5] for details). This statistic essentially measures how well the model can provide *interpolated* predicted values. Thirdly, good *extrapolation* capability testifies that the model is stable and therefore

the sample size, required to estimate its parameters, can be relatively small. A source for model instability may be high intercorrelations between the estimates of parameters (a phenomenon known as *ill-conditioning* or *multicollinearity*; see **Collinearity**). Designed orthogonality between the regressor variables when data are collected (for example, by use of **orthogonal arrays** in the experimental design) may circumvent this problem.

Other considerations and requirements may be valid too. For example, a desirable accuracy for the model's predicted value, for certain values of the regressors, may dictate a certain necessary sample size (the latter appears in the computational formula for the associated confidence interval). Further discussion of this vast area of research may be found in the above sources and the references therein.

Optimized Sample-Size Determination

In previous sections, we addressed sample sizes needed to fulfill certain constraints regarding the precision of conclusions derived from sample data. In this section, we demonstrate that sample size may be determined on the basis of optimization considerations as well. In quality and reliability engineering, the problem of optimizing sample-size determination has been addressed extensively, both with respect to sampling plans (in the context of **acceptance sampling**) and with respect to SPC. Both issues are usually dealt with, to some extent, in any textbook about statistical **quality control** (for example, [6, 7]). The reader is referred to these sources. In this section, we demonstrate how optimized sample size can be derived in the context of hypothesis testing.

Numerical Example

A certain design change in a certain product is suggested. It is believed that as a result of the change, the lifetime of the product will increase. If that increase is 50% or more, an increase of \$200 in revenue per unit is expected. Implementing the design change in the manufacturing facility is evaluated to cost \$10 per unit. It is suggested that the design change will first be tested off-line. Producing a unit in the experimental line will cost \$1000. Currently, annual production is 50 000 units. The optimized

4 Sample-Size Determination

sample size will be determined for a planning horizon of 1 year.

We determine how many units should be produced experimentally (off-line) before a decision is taken as to whether the design change is implemented. The problem can be stated as that of optimal hypothesis testing. Denoting the mean lifetime after the design change by μ and the current mean lifetime by μ_0 , the hypotheses are

$$H_0 : \mu = \mu_0; H_1 : \mu \geq 1.5\mu_0 \quad (8)$$

Let α be the probability of wrongly adopting the design change (in fact, the latter does not extend the product lifetime by the desirable 50% or over). Similarly, denote by β the probability of wrongly rejecting the design change. Let n be the sample size. The annual total cost includes the following:

- Sampling cost: $\$(1000)n$.
- Annual lost profit for wrongly accepting H_0 : $\$(200 - 10)(50\,000)$.
- Annual cost for wrongly accepting H_1 : $\$(10)(50\,000)$.

The expected cost for the planning horizon (1 year):

$$C(\alpha, \beta, n) = (10)(50\,000)\alpha + (190)(50\,000)\beta + (1000)n \quad (9)$$

where the decision variables, $\{\alpha, \beta, n\}$, are interrelated (similarly with equations (2) and (3)), by:

$$\bar{X}_{cr} = \mu_0 + \frac{\sigma}{\sqrt{n}}Z_{1-\alpha} = 1.5\mu_0 + \frac{\sigma}{\sqrt{n}}Z_{\beta} \quad (10)$$

and σ is the standard deviation of the lifetime of the product. Note that α and β , or equivalently $Z_{1-\alpha}$ and Z_{β} , uniquely determine n in equation 10.

To solve this optimization problem, the probabilities $\{\alpha, \beta\}$ may be *explicitly* represented in equation (9) by the corresponding Z values, using the highly accurate approximation for the cumulative distribution function **CDF** of the normal distribution (refer to [8]):

$$\Pr(Z \leq z) = \Phi(z) = \frac{1}{2}[1 + g(-z) - g(z)] \quad (11)$$

where

$$g(z) = \exp\{-\log(2) \exp\{\left(\frac{\alpha}{\lambda/S_1}\right) \times [(1 + S_1 z)^{\lambda/S_1} - 1] + S_2 z\}\} \quad (12)$$

and

$$\lambda = -0.61228883; S_1 = -0.11105481; S_2 = 0.44334159; \alpha = -6.37309208 \quad (13)$$

Once both equations (9) and (10) are expressed explicitly in terms of $\{Z_{1-\alpha}, Z_{\beta}, n\}$, the minimal value of equation (9), subject to constraint (10), may be identified. This solution will provide the optimal $\{Z_{1-\alpha}^*, Z_{\beta}^*, n^*\}$.

For our problem, assuming $\mu_0 = 1000$ h and $\sigma = 70$ h, we introduce for n from equation (10) into equation (9) to obtain from the latter the optimal values of:

$$n^* = 1.233 \approx 2; \alpha^* = (1.6)10^{-4}; \beta^* = (7.2)10^{-6}; x_{cr}^* = 1227 \quad (14)$$

and the total expected cost is \$1383.

Sigma Metric (Sigma Level)

Why is it Called Six Sigma?

The sigma level has been proposed as a measure of conformance quality [1]. There is a one-to-one correspondence between a process's sigma level and the fraction of nonconforming items it produces. Various definitions are current, but the basic idea is to express conformance quality as a Z value. That is, the characteristic under study is transformed such that it has a standard **normal distribution**; the position of the specification limit on this transformed scale is the Z value. For a normally distributed $N(\mu, \sigma^2)$ characteristic X with upper specification limit USL , this amounts to

$$Z = \frac{(USL - \mu)}{\sigma} \quad (1)$$

There are various conventions for dealing with the case that there is a lower and an upper specification limit. One option is to consider only the nearest specification limit:

$$Z = \min\left(\frac{(USL - \mu)}{\sigma}, \frac{(\mu - LSL)}{\sigma}\right) \quad (2)$$

Alternatively, one could compute the so-called **benchmark** Z value, which is

$$Z = \Phi^{-1}(d) \quad (3)$$

with Φ the standard normal distribution function, and d the total fraction nonconforming: $d = \Phi((LSL - \mu)/\sigma) + 1 - \Phi((USL - \mu)/\sigma)$. If X has a non-normal distribution the Z value is also computed from equation (3), be it that d should be computed differently.

If the sigma level is estimated from a data sample collected in a relatively short period, the estimate is often called the *short-term sigma level*. If one assesses the long-term sigma level from a short-term data sample, one could apply a *1.5 sigma shift*. This controversial rule of thumb says that the long-term sigma level is typically 1.5 smaller than the short-term level. Following this rule of thumb, a *six sigma process* (i.e., $Z_{\text{short term}} = 6.0$) has a long-term level $Z_{\text{long term}} = 4.5$, which corresponds to a fraction nonconforming of $d = 1 - \Phi(4.5) = 3.4$ ppm (parts per million). It is this conformance level that gave the Six Sigma method (see **Six Sigma Method**) its name.

Six Sigma Method

Six Sigma in a nutshell

From the late 1980s onwards, many companies started programmes aimed at quality and efficiency improvement under the name **Six Sigma**. Motorola was the first company to organize its improvement activities under this name, but it was, in particular, the programme's adoption in 1995 by General Electric which gave it enormous momentum. It borrows many principles and techniques from twentieth century quality engineering and industrial statistics, but its impact and completeness set it apart from earlier comparable initiatives. It could be seen as a successor of initiatives such as Taguchi's methodology, the Shainin method, and total **quality management** [1]. An overview of relevant literature is provided by Brady and Allen [2].

The approach is often characterized by its emphasis on decision making based on quantitative data, its focus on bottom-line results, and its customer driven approach. From the perspective of business economics, Six Sigma is a programme for organizing projectwise improvement of routine operations in companies. It offers a template organizational structure in which project leaders are named *black belts* or *green belts*, and project owners are named *champions*. To the project leader Six Sigma offers a stepwise strategy and an extensive collection of techniques and methods; De Koning and De Mast [3] provide a reconstruction of the method based on a multitude of sources.

A substantial part of the techniques and methods that Six Sigma prescribes for projects consist of methods borrowed from industrial statistics and quality engineering; Hoerl [4] gives an overview of a typical curriculum of a Six Sigma black belt course. Typical methods used in Six Sigma projects are statistically designed experiments, **gauge R&R** studies, and process capability analysis. In addition to these statistical and quality engineering tools the programme offers techniques borrowed from marketing and **project management**.

Six Sigma's stepwise strategy is often referred to as *DMAIC*, which stands for its main phases Define, Measure, Analyze, Improve, and Control. The objective of these phases can be described as follows [3]:

Define: problem selection and benefit analysis.

Measure: translation of the problem into a measurable form, and measurement of the current situation.

Analyze: identification of influence factors and causes that determine the behavior of critical to quality (CTQ) characteristics.

Improve: design and implementation of adjustments to the process to improve the performance of the CTQ characteristics.

Control: empirical verification of the project's results, and adjustment of the process management and control system in order that improvements are sustainable.

In many accounts these five phases are further subdivided in steps [3]. The programme prescribes that problems are quantified and parameterized in the form of indicators called *CTQ characteristics*. Improvement actions are based on the discovery of causal influence factors, sometimes called *leverage variables* or *the X's*. After 2000 the method acquired the status of standard approach in some nonmanufacturing industries as well, in particular, in healthcare and **finance** [5].

Skewness

The skewness of a random variable X is related to the third *moment* (see **Moments**) of its distribution:

$$\gamma_1 = \frac{\mu_3}{\sigma^3} \quad (1)$$

where $\mu_3 = E(X - EX)^3$ and $\sigma^2 = E(X - EX)^2$. Skewness is a measure of the symmetry of density functions, with zero skewness corresponding to a symmetrical density.

Standard Error

Estimators are random variables, and therefore they have a probability distribution. The standard error (SE) is the standard deviation of the distribution of an estimator. The smaller the standard error, the more precise (or, as it is put more commonly, *efficient*)

is the estimator. For estimators (approximately) having a **normal distribution** (such as the sample average), an approximately 95% *confidence interval* (see **Confidence Intervals**) is obtained taking plus and minus two times the standard error. See also **Estimation**.

Sum of Squares

Sums of squares are used in *analysis of variance* and regression analysis to quantify the effect of sources of variation. Such sources may be explanatory variables and factors, but also variation due to **lack of fit** (e.g., sums of squares for curvature when one fits a linear regression model to data that cannot be described by a linear model). The total sum of squares SS_{total} is given by $\sum_{i=1}^n (y_i - \bar{y})^2$. So, the total sum of squares is really the sum of squared deviations from the mean. The reason is that the simplest model for data is the sample mean. All other models should be compared with that model and hence, the sum of squares reflects the variation in the data not explained by the mean. *Analysis of variance* depends on the decomposition $SS_{\text{total}} = SS_{\text{model}} + SS_{\text{error}}$. The terms for SS_{model} depend on the precise form of the model. For example, for a balanced one-way analysis of variance model with n observations and t treatments, $SS_{\text{model}} = \sum_{i=1}^t (y_{i.} - y_{..}/n)^2$.

For unbalanced designs (i.e., different cell sizes or unequal numbers of treatment combinations), there are different decompositions of the sums of squares which unlike in the balanced case, do not yield the same result. Type I sums of squares are based on

a sequential approach, where the order of entry of terms into the overall model is important. When the order of entry of terms is based on term hierarchy, one speaks of type II sums of squares. Type III sums of squares are based on comparing estimates of marginal population means. These sums of squares are the correct choice when one is interested in the importance of *main effects* and *interactions* in unbalanced designs. Closely related to type III sums of squares are type IV sums of squares. These are developed for the case of missing cells. In case there are no missing cells, type III and type IV sums of squares coincide. We refer to [1] for practical guidance in using the correct sum of squares.

Transfer Function

The term *transfer function* is borrowed from system theory, and refers to the *mathematical equation*

that is used to represent the relation between the inputs and outputs of a system. Transfer functions are used extensively in process optimization and control.

Trimmed Mean

The trimmed mean is a robust estimator for the mean. It is computed by removing a proportion of the largest and smallest observations, and averaging the remaining values. For example, the 10% trimmed

mean of the data 6, 2, 10, 14, 9, 8, 22, 15, 13, 82, and 11 is found removing the 10% smallest and largest observations (2 and 82 in this case). From the remainder we take the average, which is 12.0.

Variance

Variance as a Property of a Distribution

Variance is the most commonly used measure for dispersion. Given a random variable X , with **probability density function** $f(x)$ and mean μ , the variance is defined as

$$\sigma_x^2 = E(X - \mu)^2 = \int_{-\infty}^{\infty} (x - \mu)^2 f(x) dx \quad (1)$$

for a continuous variable, and by

$$\sigma_x^2 = E(X - \mu)^2 = \sum_{j=0}^{\infty} (x - \mu)^2 f(x), \quad x \geq 0 \quad (2)$$

for a nonnegative discrete variable (where $f(x)$ in equation (2) is the probability function). The variance is thus the second central moment (*see Moments*) of the distribution.

A short formula to calculate the variance, based on the first two noncentral **moments**, is

$$\sigma_x^2 = E(X^2) - [E(X)]^2 \quad (3)$$

The variance σ_T^2 of a linear transformation $T = a_0 + a_1 X$ is $\sigma_T^2 = a_1^2 \sigma_x^2$.

Let $\{X_1, X_2, \dots, X_k\}$ be k independent random variables, with standard deviations $\{\sigma_1, \sigma_2, \dots, \sigma_k\}$ respectively. Define the weighted sum:

$$S = a_0 + a_1 X_1 + \dots + a_k X_k \quad (4)$$

The variance of S , σ_S^2 , is

$$\sigma_S^2 = a_1^2 \sigma_1^2 + a_2^2 \sigma_2^2 + \dots + a_k^2 \sigma_k^2 \quad (5)$$

In case the $\{X_1, X_2, \dots, X_k\}$ are correlated, with ρ_{ij} denoting the **correlation** between X_i and X_j , the variance of S is

$$\begin{aligned} \text{Var} \left(a_0 + \sum_{i=1}^k a_i X_i \right) &= \sum_{i=1}^k a_i^2 \text{Var}(X_i) \\ &+ 2 \sum_{i=1}^{k-1} \sum_{j=i+1}^k (a_i a_j \sigma_i \sigma_j \rho_{ij}) \end{aligned} \quad (6)$$

A *random* sum is defined by

$$S = X_1 + X_2 + \dots + X_M \quad (7)$$

where $\{X_1, X_2, \dots, X_M\}$ are independently and identically distributed (i.i.d) random variables, each with mean μ_X and variance σ_X^2 , and M is a random variable with a mean, μ_M , and a variance, σ_M^2 (M is assumed to be independent of any X_i). The mean and variance of S are, respectively,

$$\mu_S = \mu_M \mu_X \quad (8)$$

$$\sigma_S^2 = \mu_M \sigma_X^2 + \sigma_M^2 \mu_X^2 \quad (9)$$

Let $\{X, Y\}$ be a pair of random variables with finite variances. Given the conditional variance of Y , $V(Y|X = x)$, and the conditional mean of Y , $E(Y|X = x)$, the *unconditional* variance of Y is:

$$V(Y) = E_x\{V(Y|X = x)\} + V_x\{E(Y|X = x)\} \quad (10)$$

where E_x is the expected value, calculated with respect to X , and V_x is the variance, calculated with respect to X . Equation (10) expresses the *law of total variance*.

For a catalog of some probability density functions, and the associated formulas for variance calculation, refer to **Probability Density Functions**.

Variance as a Population Parameter

Suppose that we have a population of N units, and on this population we have defined a variable, X . The population variance, σ_p^2 , is calculated by

$$\sigma_p^2 = \frac{1}{N} \sum_{i=1}^N (X_i - \mu_p)^2 \quad (11)$$

where X_i is the X value associated with unit i , and μ_p is the population mean.

The Sample Variance

The sample variance is a statistic commonly used as an unbiased, consistent, and minimum-variance estimator of the population variance. Suppose that a random sample of n observations have been collected, and denote the value of the i th observation by X_i . An

2 Variance

unbiased sample estimator of the population variance, based on a sample with n observations, is

$$\hat{\sigma}_x^2 = \frac{1}{(n-1)} \sum_{i=1}^n (X_i - \hat{\mu})^2 \quad (12)$$

where $\hat{\mu}$ is the sample average. Note, that although this sample estimator of the population variance is unbiased, its square root, often used to estimate the standard deviation, is biased. In **statistical process control** (SPC), the sample range is often employed in a formula that estimates the standard deviation.

Equation (12) is a variance estimator for an infinite population or a population that is large enough to be considered so. When the population is finite, random sampling from the population may be with replacement (each sampled unit is *thrown* back into the population for a possible repeat sampling) or without replacement. For the latter case, equation (12) is no longer appropriate to estimate the variance. It may be shown that the expected value of the statistic in equation (12) is no longer the population

variance but rather (refer to [1, p. 171]):

$$E(\hat{\sigma}_x^2) = \sigma_x^2 \left(1 + \frac{1}{N-1}\right) \quad (13)$$

where N is the *population* size. Similarly, the variance of the sample mean for a random sample of n items, drawn without replacement, is [1, p. 170]

$$V(\bar{X}) = \frac{\sigma_x^2}{n} \left(1 - \frac{n-1}{N-1}\right) \quad (14)$$

Equations (13) and (14) are often useful in sampling without replacement conducted within **acceptance sampling**.

HAIM SHORE

Measures of Association

Introduction

Measures of association quantify the statistical dependence of two or more categorical variables. Many measures of association have been proposed; in this article, we restrict our attention to the ones that are most commonly used. We broadly divide the measures into those suitable for (a) unordered (nominal) categorical variables, and (b) ordered categorical variables.

Measures of Association for Unordered Categorical Variables

As an example, consider the contingency table shown in Table 1, with sex (s) as the row variable and employment status (e) as the column variable.

Measures Based on the Odds Ratio

The odds that an event will occur are computed by dividing the probability that the event will occur by the probability that the event will not occur. For males, the odds of being employed equal the probability of being employed divided by the probability of not being employed:

$$\begin{aligned} odds_{y|m} &= \frac{p(y|m)}{1 - p(y|m)} = \frac{p(y|m)}{p(n|m)} \\ &= \frac{42/75}{33/75} = \frac{0.56}{0.44} = 1.27 \end{aligned} \quad (1)$$

Similarly, for females:

$$\begin{aligned} odds_{y|f} &= \frac{p(y|f)}{1 - p(y|f)} = \frac{p(y|f)}{p(n|f)} \\ &= \frac{40/165}{125/165} = \frac{0.242}{0.758} = 0.319 \end{aligned} \quad (2)$$

These odds are large when employment is likely, and small when it is unlikely. The odds can be interpreted as the number of times that employment occurs for each time it does not. For example, since the odds of employment for males is 1.27, approximately 1.27 males are employed for every unemployed male, or,

Table 1 Employment status of males and females

		Employment status		Total
		Employed (y)	Not employed (n)	
Sex	Male (m)	42	33	75
	Female (f)	40	125	165
	Total	82	58	40

in round numbers, 5 males are employed for every four males that are unemployed. For females, there is approximately one employed female for every three unemployed females.

The association between sex and employment status can be expressed by the degree to which the two odds differ. This difference can be summarized by the odds ratio (α):

$$\alpha = \frac{odds_{y|f}}{odds_{y|m}} = \frac{p(y|f)/p(n|f)}{p(y|m)/p(n|m)} = \frac{1.27}{0.32} = 3.98 \quad (3)$$

This odds ratio indicates that for every one employed female, there are four employed males. Although not necessary, it is customary to place the larger of the two odds in the numerator.

Odds ratios are not symmetric around one: An odds ratio larger than one by a given amount indicates a smaller effect than an odds ratio smaller than one by the same amount [1]. While the magnitude of an odds ratio less than one is restricted to the range between zero and one, odds ratios greater than one and are not restricted, allowing the ratio to potentially take on any value. If the natural logarithm ($\ln$) of the odds ratio is taken, the odds ratio is symmetric above and below one, with $\ln(1) = 0$. For example, to take the 2×2 example above, the odds ratio of a male being employed, compared to a female, was 3.98. If we reverse that and take the odds ratio of a female being employed compared to a male, it is $0.32/1.27 = 0.25$. These ratios are clearly not symmetric about 1.00. However, $\ln(3.98) = 1.38$ and $\ln(0.25) = -1.38$, and these ratios are symmetric.

Yule's Q Coefficient of Association. Both α and $\ln(\alpha)$ range from $-\infty$ to $+\infty$. to restrict the odds ratio within the interval -1 to $+1$, Yule introduced the coefficient of association, Q , for 2×2 tables. Its

2 Measures of Association

definition is [2]:

$$Q = \frac{n_{11}n_{22} - n_{12}n_{21}}{n_{11}n_{22} + n_{12}n_{21}} = \frac{\alpha - 1}{\alpha + 1} \quad (4)$$

Therefore, if odds ratio (α) expressing the relationship between sex and employment is 3.98,

$$\begin{aligned} Q &= \frac{(42)(125) - (33)(40)}{(42)(125) + (33)(40)} \\ &= \frac{3.98 - 1}{3.98 + 1} = 0.59 \end{aligned} \quad (5)$$

Yule's Q is algebraically equal to the 2×2 Goodman–Kruskal γ coefficient (described below), and thus measures the degree of concordance or discordance between two variables.

Yule's Coefficient of Colligation. As an alternative to Q , Yule proposed the *coefficient of colligation* [2]:

$$\hat{Y} = \frac{\sqrt{n_{11}n_{22}} - \sqrt{n_{12}n_{21}}}{\sqrt{n_{11}n_{22}} + \sqrt{n_{12}n_{21}}} = \frac{\sqrt{a} - 1}{\sqrt{a} + 1} \quad (6)$$

The coefficient of colligation between sex and employment is

$$\begin{aligned} \hat{Y} &= \frac{\sqrt{(42)(125)} - \sqrt{(33)(40)}}{\sqrt{(42)(125)} + \sqrt{(33)(40)}} \\ &= \frac{\sqrt{3.98} - 1}{\sqrt{3.98} + 1} = 0.33 \end{aligned} \quad (7)$$

The coefficient of colligation has a different interpretation than the coefficient of association, and is interpreted as a Pearson product–moment **correlation** coefficient r (see below), but is not algebraically equivalent to one.

Both Q and $\hat{Y}$ are symmetric measures of association, and are invariant under changes in the ordering of rows and columns.

Measures Based on Pearson's χ^2

$$\chi^2 = \sum_i \sum_j \frac{(n_{ij} - \hat{n}_{ij})^2}{n_{ij}} \quad (8)$$

where $\hat{n}_{ij}$ is the expected frequency in cell ij , and can be usefully transformed into several measures of association [3].

The Φ Coefficient. The ϕ coefficient is defined as [4]:

$$\Phi = \sqrt{\frac{\chi^2}{N}} \quad (9)$$

For sex and employment,

$$\Phi = \sqrt{\frac{23.12}{240}} = 0.31 \quad (10)$$

The Φ coefficient can vary between 0 and 1, and is algebraically equivalent to $|r|$. However, the lower and upper limits of Φ in a 2×2 table are dependent on two conditions. In order for Φ to equal -1 or $+1$, (a) $(n_{11} + n_{12}) = (n_{21} + n_{22})$, and (b) $(n_{11} + n_{21}) = (n_{12} + n_{22})$.

The Pearson Product-Moment Correlation Coefficient. The general formula for the *Pearson product–moment correlation coefficient* is

$$r = \frac{\sum_i (X_i - \bar{X})(Y_i - \bar{Y})}{N s_x s_y} \quad (11)$$

where X and Y are two continuous, interval-level variables. The categories of a dichotomous variable can be coded 0 and 1, and used in the formula for r . In a 2×2 contingency table, the calculations reduce to [5]:

$$r = \frac{n_{11}n_{22} - n_{12}n_{21}}{\sqrt{n_{1+}n_{2+}n_{+1}n_{+2}}} \quad (12)$$

For sex and employment, $r = \{(42)(125) - (33)(40) / \sqrt{[(75)(165)(82)(158)]}\} = 0.31$.

A symmetric measure of association is also invariant to row and column order, r varies between -1 to $+1$. From the formula, it is apparent that $r = 1$ if $n_{12} = n_{21} = 0$, and $r = -1$ if $n_{11} = n_{22} = 0$. In a standardized 2×2 table, where each marginal probability = 0.5, $r = \hat{Y}$; otherwise $|r| < |\hat{Y}|$ except

when the variables are independent or completely related.

Measures of Predictive Association

Another class of measures of association for nominal variables is measures of prediction analogous in concept to the multiple correlation coefficient or R^2 in regression analysis [2](see **Coefficient of Determination (R^2)**). When there is an association between two nominal variables X and Y , then knowledge about X allows one to obtain knowledge about Y , more knowledge than would have been available without X . Let Δ_Y be the dispersion of Y and $\Delta_{Y.X}$ be the conditional dispersion of Y given X . A measure of prediction

$$\phi_{Y.X} = 1 - \frac{\Delta_{Y.X}}{\Delta_Y} \quad (13)$$

compares the conditional dispersion of Y given X to the unconditional dispersion of Y , similar to how the multiple correlation coefficient compares the conditional variance of the dependent variable to its unconditional variance [3]. When $\phi_{Y.X} = 0$, X and Y are independently distributed; when $\phi_{Y.X} = 1$, X is a perfect predictor of Y .

We describe four measures that operationalize the idea underlying $\phi_{Y.X} = 0$.

The first measure is the *asymmetric lambda coefficient* of Goodman and Kruskal [6]:

$$\begin{aligned} \lambda(Y = c|X = r) &= \frac{\sum_i \max_j p_{ij} - \max_j p_{+j}}{1 - \max_j p_{+j}} \\ \lambda(X = r|Y = c) &= \frac{\sum_j \max_i p_{ij} - \max_i p_{+i}}{1 - \max_i p_{+i}} \end{aligned} \quad (14)$$

The second is the *symmetric lambda coefficient* (λ) of Goodman and Kruskal [6]:

$$\lambda = \frac{\sum_i \max_j p_{ij} + \sum_j \max_i p_{ij} - \max_j p_{+j} - \max_i p_{+i}}{2 - \max_j p_{+j} - \max_i p_{+i}} \quad (15)$$

The third is the *asymmetric uncertainty coefficient* of Theil [7]:

$$\begin{aligned} U(Y = c|X = r) &= \frac{\left(-\sum_i (p_{i+}) \ln(p_{i+}) \right) + \left(-\sum_j (p_{+j}) \ln(p_{+j}) \right) - \left(-\sum_i \sum_j (p_{ij}) \ln(p_{ij}) \right)}{-\sum_j (p_{+j}) \ln(p_{+j})} \\ U(X = r|Y = c) &= \frac{\left(-\sum_i (p_{i+}) \ln(p_{i+}) \right) + \left(-\sum_j (p_{+j}) \ln(p_{+j}) \right) - \left(-\sum_i \sum_j (p_{ij}) \ln(p_{ij}) \right)}{-\sum_i (p_{i+}) \ln(p_{i+})} \end{aligned} \quad (16)$$

The fourth measure of predictive association is U , Theil's *symmetric uncertainty coefficient* [7]:

$$U = \frac{2 \left[\left(-\sum_i (p_{i+}) \ln(p_{i+}) \right) + \left(-\sum_j (p_{+j}) \ln(p_{+j}) \right) - \left(-\sum_i \sum_j (p_{ij}) \ln(p_{ij}) \right) \right]}{\left(-\sum_i (p_{i+}) \ln(p_{i+}) \right) + \left(-\sum_j (p_{+j}) \ln(p_{+j}) \right)} \quad (17)$$

We use the contingency table shown in Table 2 to illustrate, in turn, the computation of the four measures of predictive association.

The first measure, asymmetric $\lambda(Y|X)$, is interpreted as the relative decrease in the probability of incorrectly predicting the column variable Y between not knowing X and knowing X . As such, lambda can also be interpreted as a proportional reduction in

4 Measures of Association

Table 2 The computation of the four measures of predictive association

	Y_1	Y_2	Y_3	Y_4	Total
X_1	28	32	49	36	145
X_2	44	21	17	12	94
X_3	46	31	53	63	193
Total	118	84	119	111	

variation measure – how much of the variance in one variable is accounted for by the other? In the equation for $\lambda(Y|X)$, $1 - \max p_{ij}$ is the minimum probability of error from the prediction that Y is a function of X , and $1 - \max_j p_{+j}$ is the minimum probability of error from a prediction that Y is a constant over X . For the data we obtain:

$$\begin{aligned}\lambda(Y|X) &= \frac{((49 + 44 + 63)/432) - (119/432)}{1 - (119/432)} \\ &= \frac{0.36 - 0.28}{1 - 0.28} = 0.11\end{aligned}\quad (18)$$

Thus, there is an 11% improvement in predicting the column variable Y given the knowledge of the row variable X . Asymmetric λ has the range $0 \leq \lambda(Y|X) \leq 1$.

In general, $\lambda(Y|X) \neq \lambda(X|Y)$; $\lambda(X|Y)$ is the relative decrease in the probability of incorrectly predicting the row variable X between not knowing Y and knowing Y – hence, the term “asymmetric”. For these data,

$$\begin{aligned}\lambda(X|Y) &= \frac{((46 + 32 + 53 + 63)/432) - (193/432)}{1 - (193/432)} \\ &= \frac{0.45 - 0.44}{1 - 0.44} = 0.02\end{aligned}\quad (19)$$

Symmetric λ is the average of the two asymmetric lambdas and has the range $0 \leq \lambda \leq 1$. For our example,

$$\lambda = \frac{0.36 + 0.45 - 0.28 - 0.44}{2 - 0.28 - 0.44} = \frac{0.09}{1.28} = 0.07 \quad (20)$$

Theil’s asymmetric uncertainty coefficient, $U(Y|X)$, is the proportion of uncertainty in the column variable Y that is explained by the row variable X , or, alternatively, $U(X|Y)$ is the proportion of uncertainty in the row variable X that is explained

by the column variable Y . The asymmetric uncertainty coefficient has the range $0 \leq U(Y|X) \leq 1$. For $U(Y|X)$, we obtain for these data:

$$U(Y|X) = \frac{(1.06) + (1.38) - (2.40)}{1.38} = 0.03 \quad (21)$$

and for $U(X|Y)$,

$$U(X|Y) = \frac{(1.06) + (1.38) - (2.40)}{1.06} = 0.04 \quad (22)$$

The symmetric U is computed as

$$U = \frac{2[(1.06) + (1.38) - (2.40)]}{(1.06) + (1.38)} = 0.03 \quad (23)$$

Both the asymmetric and symmetric uncertainty coefficients have the range $0 \leq U \leq 1$.

The quantities in the numerators of the equations for the asymmetric lambda and uncertainty coefficients are interpreted as measures of variation for nominal responses: In the case of lambda coefficients, the variation measure is called the *Gini concentration*, and the variation measure used in the uncertainty coefficients is called the *entropy* [2]. More specifically, in $\lambda(Y|X)$, the numerator represents the variance of the Y or column variable:

$$V(Y) = \sum_i \max_j p_{ij} - \max_j p_{+j} \quad (24)$$

and in $\lambda(X|Y)$, the numerator represents the variance of the X or row variable:

$$V(X) = \sum_j \max_i p_{ij} - \max_i p_{i+} \quad (25)$$

Analogously, the numerator of $U(Y|X)$ is the variance of Y ,

$$\begin{aligned}V(Y) &= (-\sum_i (p_{i+}) \ln(p_{i+})) \\ &\quad + (-\sum_j (p_{+j}) \ln(p_{+j})) \\ &\quad - (-\sum_i \sum_j (p_{ij}) \ln(p_{ij}))\end{aligned}\quad (26)$$

and the numerator of $U(X|Y)$ is the variance of X ,

$$\begin{aligned}V(X) &= (-\sum_i (p_{i+}) \ln(p_{i+})) \\ &\quad + (-\sum_j (p_{+j}) \ln(p_{+j})) \\ &\quad - (-\sum_i \sum_j (p_{ij}) \ln(p_{ij}))\end{aligned}\quad (27)$$

However, in these measures, there is a positive relationship between the number of categories and the magnitude of the variation, thus introducing ambiguity in evaluating both the variance of the variables and their relationship.

Measures of Association for Ordered Categorical Variables

Measures of Concordance/Discordance

A pair of observations is *concordant* if the observation that ranks higher on X also ranks higher on Y . A pair of observations is *discordant* if the observation that ranks higher on X ranks lower on Y . The number of concordant pairs is

$$C = \sum_{i < i'} \sum_{j < j'} n_{ij} n_{i'j'} \quad (28)$$

where the first summation is over all rows $i < i'$, and the second summation is over all pairs of columns $j < j'$. The number of discordant pairs is

$$D = \sum_{i < i'} \sum_{j > j'} n_{ij} n_{i'j'} \quad (29)$$

where the first summation is over all rows $i < i'$, and the second summation is over all columns $j > j'$.

To illustrate the calculation of C and D , consider the 3×3 contingency table shown in Table 3 cross-classifying income with education.

In this table, the number of concordant pairs is

$$\begin{aligned} C &= 302(331 + 250 + 155 + 185) \\ &+ 105(250 + 185) + 409(155 + 185) \\ &+ 331(185) = 524\,112 \end{aligned} \quad (30)$$

Note that the process of identifying concordant pairs amounts to taking each cell frequency (e.g., 302) in turn, and multiplying that frequency by each of the cell frequencies “southeast” of it (e.g., 331, 250, 155, 185).

The number of discordant pairs is

$$\begin{aligned} D &= 23(409 + 331 + 15 + 155) \\ &+ 105(409 + 15) + 250(15 + 155) \\ &+ 331(15) = 112\,915 \end{aligned} \quad (31)$$

Discordant pairs can readily be identified by taking each cell frequency (e.g., 23) in turn, and multiplying that cell frequencies by each of the cell frequencies “southwest” of it (e.g., 409, 331, 15, 155).

Let $n_{i+} = \sum_j n_{ij}$ and $n_{+j} = \sum_i n_{ij}$. We can express the total number of pairs of observations as

$$\frac{n(n-1)}{2} = C + D + T_X + T_Y - T_{XY} \quad (32)$$

where $T_X = \sum_i n_i(n_{i+} - 1)/2$ is the number of pairs tied on the row variable X , $T_Y = \sum_j n_j(n_{+j} - 1)/2$ is the number of pairs tied on the column variable Y , and $T_{XY} = \sum_i \sum_j n_{ij}(n_{ij} - 1)/2$ is the number of pairs from a common cell (tied on X and Y). In this formula for $n(n-1)/2$, T_{XY} is subtracted because pairs tied on both X and Y have been counted twice, once in T_X and once in T_Y . Therefore,

$$\begin{aligned} T_X &= \frac{(430 \times 429) + (990 \times 989) \\ &\quad + (355 \times 354)}{2} \\ &= 644\,625 \end{aligned} \quad (33)$$

Table 3 Income for three levels of education

		Income				
		Low	Medium	High	Total	Proportion
Education	LT than high school	302	105	23	430	0.243
	High school	409	331	250	990	0.557
	GT than high school	15	155	185	355	0.200
	Total	726	591	458	1775	1.00
	Proportion	0.409	0.333	0.258	1.00	

$$T_Y = \frac{(726 \times 725) + (591 \times 590) + (458 \times 457)}{2} = 542\,173 \quad (34)$$

$$T_{XY} = \frac{(302 \times 301) + (105 \times 104) + \dots + (185 \times 184)}{2} = 249\,400 \quad (35)$$

$$\begin{aligned} \frac{n(n-1)}{2} &= (524\,112) + (112\,915) + (644\,625) \\ &\quad + (542\,173) - (249\,400) \\ &= 1\,574\,425 \end{aligned} \quad (36)$$

Kendall's τ Statistics. Several measures of concordance/discordance are based on the difference $C - D$. Kendall's three *tau* (τ) statistics are among the most well known of these, and can be applied to $r \times c$ contingency tables with $r \geq 2$ and $c \geq 2$. The row and column variables do not have to have the same number of categories. The (τ) statistics have the range $-1 \leq 0 \leq +1$.

The three (τ) statistics are [8]:

$$\tau_a = \frac{2(C - D)}{N(N - 1)} \quad (37)$$

$$\tau_b = \frac{(C - D)}{\sqrt{[(C + D + T_Y - T_{XY})(C + D + T_X - T_{XY})]}} \quad (38)$$

$$\tau_c = \frac{2m(C - D)}{N^2(m - 1)} \quad (39)$$

where m = the number of rows or column, whichever is smaller. For our data, the tau statistics are equal to

$$\tau_a = \frac{2(524\,112 - 112\,915)}{1775(1775 - 1)} = 0.26 \quad (40)$$

$$\begin{aligned} \tau_b &= \frac{(524\,112 - 112\,915)}{\sqrt{[(524\,112 + 112\,915 + 542\,173 - 249\,900) \\ &\quad \sqrt{(524\,112 + 112\,915 + 644\,625 - 249\,900)]}} \\ &= 0.42 \end{aligned} \quad (41)$$

$$\tau_c = \frac{3 \times 2(524\,112 - 112\,915)}{1775^2(3 - 1)} = 0.39 \quad (42)$$

One note of qualification is that $\tau - a$ assumes there are no tied observations; thus, strictly speaking, it is not applicable to contingency tables. It is generally more useful as a measure of rank correlation. For 2×2 tables, τ_b simplifies to the Pearson product-moment correlation obtained by assigning any scores to the rows and columns consistent with their orderings.

Goodman and Kruskal's γ . Goodman and Kruskal suggested yet another measure, *gamma* (γ) based on $C - D$ [6]:

$$\gamma = \frac{C - D}{C + D} \quad (43)$$

For our example data, $\gamma = (524\,112 - 112\,915)/(524\,112 + 112\,915) = 0.65$. γ has the range $-1 \leq 0 \leq +1$, equal to $+1$ when the data are concentrated in the upper-left to lower-right diagonal, and equal to -1 for the converse pattern. Although γ does equal zero when the two variables are independent, two variables can be completely dependent and still have a value of γ less than unity. For 2×2 tables, γ is equal to Yule's Q .

Measures Based on Derived Scores

Some methods for measuring the association between ordinal variables require assigning scores to the levels of the ordinal variables. When a contingency table is involved, scale values are assigned to row and column categories, the data are treated as a grouped frequency distribution, and the Pearson product-moment correlation is computed.

Specifically, let x_i and y_j be the values assigned to the rows and columns. The Pearson product-moment correlation for grouped data is then

$$r = \frac{C P_{XY}}{\sqrt{SS_X SS_Y}} \quad (44)$$

where $C P_{XY}$ is the sum of cross products,

$$C P_{XY} = \sum_{i,j} x_i y_j n_{ij} - \frac{\left(\sum_i x_i n_{i+} \right) \left(\sum_j y_j n_{+j} \right)}{n_{++}} \quad (45)$$

and SS_X and SS_Y are the sums of squares,

$$SS_X = \sum_i x_i^2 n_{i+} - \frac{\left(\sum_i x_i n_{i+}\right)^2}{n_{++}} \quad (46)$$

$$SS_Y = \sum_j y_j^2 n_{+j} - \frac{\left(\sum_j y_j n_{+j}\right)^2}{n_{++}} \quad (47)$$

Therefore, if for our 3×3 contingency table for income and education, we assign the values, “1”, “2”, and “3” to the three levels of each variable, we have

$$CP_{XY} = 6863 - \frac{(3475)(3282)}{1775} = 437.68 \quad (48)$$

$$SS_X = 7585 - \frac{(3475)^2}{1775} = 781.83 \quad (49)$$

$$SS_Y = 7212 - \frac{(3282)^2}{1775} = 1143.54 \quad (50)$$

$$r = \frac{437.68}{\sqrt{(781.83)(1143.54)}} = 0.46 \quad (51)$$

The value of $r = 0.46$ is also known as the *Spearman rank correlation coefficient* r_s , sometimes referred to as Spearman’s rho [9]. The Spearman rank correlation coefficient can also be computed by using:

$$r_s = \frac{6 \sum d^2}{n(n^2 - 1)} \quad (52)$$

where d is the difference in the rank scores between X and Y . Computed by using this formula,

$$r_s = \frac{6(20706)^2}{1775(1775^2 - 1)} = 0.46 \quad (53)$$

Instead of using the rank scores of “1”, “2”, and “3” directly, we can use *ridit scores* [10]. Ridit scores are cumulative probabilities; each ridit score represents the proportion of observations below category j plus half the proportion within j . We illustrate the calculation of ridit scores using the income and education contingency table. Beneath

each marginal total is the proportion of observations in the row or column. The ridit score for the low income category is $0.5(0.409) = 0.205$; for medium income, $0.409 + 0.5(0.333) = 0.576$; and for high income, the ridit score is $0.409 + 0.333 + 0.5(0.258) = 0.871$. The ridit scores for less than high school education is $0.5(0.243) = 0.122$; for high school education, $0.243 + 0.5(0.557) = 0.522$; and for greater than high school education, the ridit score is $0.243 + 0.557 + 0.5(0.200) = 0.900$. Applying the Pearson product-moment correlation formula to the ridit scores, we obtain $r_s = 0.47$.

Probability Density Functions

Introduction

Probability density functions (PDFs) (*see* **Probability Density Function (PDF)**) are mathematical formulas that provide information about how the values of random variables are distributed. For a discrete random variable (one taking only particular values within some interval), the formula gives the probability of each value of the variable. For a continuous random variable (one that can take any value within some interval), the formula specifies the probability that the variable falls within a particular range. This is given by the area under the curve defined by the **PDF**. Here a list of the most commonly encountered PDFs and their most important properties is provided. More comprehensive accounts of density functions can be found in [1, 2].

Probability Density Functions for Discrete Random Variables

Bernoulli

A simple PDF for a random variable, X , that can take only two values, for example, 0 or 1. Tossing a single coin provides a simple example. Explicitly the density is defined as

$$P(X = x_1) = 1 - P(X = x_0) = p \quad (1)$$

where x_1 and x_0 are the two values that the random variable can take (often labeled as “success” and “failure”) and P denotes probability. The single parameter of the Bernoulli density function is the probability of a “success”, p . The expected value of X is p and its variance is $p(1 - p)$.

Binomial

A PDF for a random variable, X , that is the number of “successes” in a series of n independent Bernoulli variables. The number of heads in n tosses of a coin provides a simple practical example. The binomial density function is given by

$$P(X = x) = \frac{n!}{x!(n-x)!} p^x (1-p)^{n-x},$$

$$x = 0, 1, 2, \dots, n \quad (2)$$

The probability of the random variable taking a value in some range of values is found by simply summing the PDF over the required range. The expected value of X is np and its variance is $np(1 - p)$. Some examples of binomial density functions are shown in Figure 1. The binomial is important in assigning probabilities to simple chance events such as the probability of getting three or more sixes in 10 throws of a fair die, in the development of simple statistical significance tests such as the sign test (*see* **Nonparametric Tests**) and as the error distribution used in logistic regression. See also the multinomial distribution defined later in this article.

Geometric

The PDF of a random variable, X , that is the number of “failures” in a series of independent Bernoulli variables before the first “success”. An example is provided by the number of tails before the first head, when a coin is tossed a number of times. The density function is given by

$$P(X = x) = p(1 - p)^{x-1}, \quad x = 1, 2, \dots \quad (3)$$

The geometric density function possesses a *lack of memory property*, by which we mean that in a series of Bernoulli variables the probability of the next n trials being “failures” followed immediately by a “success” remains the same geometric PDF regardless of what the previous trials were. The mean of X is $1/p$ and its variance is $(1 - p)/p^2$. Some examples of geometric density functions are shown in Figure 2.

Negative Binomial

The PDF of a random variable, X , that is the number of “failures” in a series of independent Bernoulli variables before the k th “success”. For example, the number of tails before the 10th head in a series of coin tosses. The density function is given by

$$P(X = x) = \frac{(k+x-1)!}{(x-1)!k!} p^k (1-p)^x, \quad x = 0, 1, 2, \dots \quad (4)$$

2 Probability Density Functions

Figure 1 Examples of binomial density functions

Figure 2 Examples of geometric density functions

Figure 3 Examples of negative binomial density functions

The mean of X is $k(1-p)/p$ and its variance is $k(1-p)/p^2$. Some examples of the negative binomial distribution are given in Figure 3. The density is important in discussions of overdispersion in the context of **Generalized Linear Models**.

Hypergeometric

A PDF associated with *sampling without replacement* from a population of finite size. If the population consists of r elements of one kind and $N-r$ of another, then the hypergeometric is the PDF of the random variable X defined as the number of elements of the first kind when a random sample of n is drawn. The density function is given by

$$P(X = x) = \frac{r!(N-r)!}{x!(r-x)!(n-x)!(N-r-n+x)!} \frac{N!}{n!(N-n)!} \quad (5)$$

The mean of X is nr/N and its variance is $(nr/N)(1-r/n)[(N-n)/(N-1)]$. The hypergeometric density function is the basis of Fisher's

exact test used in the analysis of sparse contingency tables.

Poisson

A PDF that arises naturally in many instances, particularly as a probability model for the occurrence of rare events, for example, the emission of radioactive particles. In addition, the Poisson density function is the limiting distribution of the binomial when p is small and n is large. The Poisson density function for a random variable X taking integer values from 0 to ∞ is defined as

$$P(X = x) = \frac{e^{-\lambda} \lambda^x}{x!}, \quad x = 0, 1, 2, \dots, \infty \quad (6)$$

The single parameter of the Poisson density function, λ , is both the expected value and variance, that is, the mean and variance of a Poisson random variable are equal. Some examples of Poisson density functions are given in Figure 4.

4 Probability Density Functions

Figure 4 Examples of Poisson density functions

Probability Density Functions for Continuous Random Variables

Normal

The PDF, $f(x)$, of a continuous random variable X defined as follows

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left[-\frac{1}{2} \frac{(x - \mu)^2}{\sigma^2}\right] \quad (7)$$

$-\infty < x < \infty$

where μ and σ^2 are, respectively the mean and variance of X . When the mean is zero and the variance one, the resulting density is labeled as the *standard normal*. The normal density function is bell-shaped as is seen in Figure 5, where a number of normal densities are shown.

In the case of continuous random variables, the probability that the random variable takes a particular value is strictly zero; nonzero probabilities can only be assigned to some range of values of the variable. So, for example, we say that $f(x)dx$ gives the probability of X falling in the very small interval,

Figure 5 Normal density functions

dx , centered on x , and the probability that X falls in some interval, $[A, B]$ say, is given by integrating $f(x)dx$ from A to B .

The normal density function is ubiquitous in statistics. The vast majority of statistical methods are based on the assumption of a normal density for the observed data or for the error terms in models for the data. In part this can be justified by an appeal to the central limit theorem. The density function first

appeared in the papers of de Moivre at the beginning of the eighteenth century and some decades later was given by Gauss and Laplace in the theory of errors and the least squares method. For this reason, the normal is also often referred to as the *Gaussian* or *Gaussian–Laplace*.

Uniform

The mean of such a random variable is having constant probability over an interval. The density function is given by

$$f(x) = \frac{1}{\beta - \alpha}, \quad \alpha < x < \beta \quad (8)$$

The mean of the density function is $(\alpha + \beta)/2$ and the variance is $(\beta - \alpha)^2/12$. The most commonly encountered version of this density function is one in which the parameters α and β take the values 0 and 1 respectively, and is used in generating quasi-random numbers.

Exponential

The PDF of a continuous random variable, X , taking only positive values. The density function is given by

$$f(x) = \lambda e^{-\lambda x}, \quad x > 0 \quad (9)$$

The single parameter of the exponential density function, λ , determines the shape of the density function, as we see in Figure 6, where a number of different exponential density functions are shown. The mean of an exponential variable is $1/\lambda$ and the variance is $1/\lambda^2$.

The exponential density plays an important role in some aspects of reliability engineering and also gives the distribution of the time intervals between independent consecutive random events such as particles emitted by radioactive material.

Beta

A PDF for a continuous random variable, X , taking values between 0 and 1. The density function is defined as

$$f(x) = \frac{\Gamma(p+q)}{\Gamma(p)\Gamma(q)} x^{p-1} (1-x)^{q-1}, \quad 0 < x < 1$$

Figure 6 Exponential density functions

where $p > 0$ and $q > 0$ are parameters that define particular aspects of the shape of the beta density and Γ is the gamma function (see [3]). The mean of a beta variable is $p/(p+q)$ and the variance is $pq/(p+q)^2(p+q+1)$.

Gamma

A PDF for a random variable X that can take only positive values. The density function is defined as

$$f(x) = \frac{1}{\Gamma(\alpha)} x^{\alpha-1} e^{-x}, \quad x > 0 \quad (11)$$

where the single parameter, α , is both the mean of X and also its variance.

The gamma density function can often act as a useful model for a variable that cannot reasonably be assumed to have a normal density function because of its positive **Skewness**.

Chi-Squared

The PDF of the **sum of squares** of a number (ν) of independent standard normal variables given by

$$f(x) = \frac{1}{2^{\nu/2} \Gamma(\nu/2)} x^{(\nu-2)/2} e^{-x/2}, \quad x > 0 \quad (12)$$

that is, a gamma density with $\alpha = \nu/2$. The parameter ν is usually known as the **degrees of freedom** of the density. The mean and variance of a χ^2 distribution are ν and 2ν respectively. This density function

6 Probability Density Functions

arises in many areas of statistics, most commonly as the null distribution of the chi-squared goodness of fit statistics, or as the distribution associated with estimators of variance.

Student's T

The PDF of a variable defined as

$$t = \frac{\bar{X} - \mu}{s/\sqrt{n}} \quad (13)$$

where $\bar{X}$ is the arithmetic mean of n observations from a normal density with mean μ and s is the sample standard deviation. The density function is given by

$$f(t) = \frac{\Gamma\left\{\frac{1}{2}(\nu+1)\right\}}{(\nu\pi)^{1/2}\Gamma\left(\frac{1}{2}\nu\right)} \left(1 + \frac{t^2}{\nu}\right)^{-\frac{1}{2}(\nu+1)},$$

$$-\infty < t < \infty \quad (14)$$

where $\nu = n - 1$. The shape of the density function varies with ν , and as ν gets larger the shape of the t -density function approaches that of a standard normal. This density function is the null distribution of Student's t -statistic used for testing hypotheses about population means (see **Parametric Tests**).

Fisher's F

The PDF of the ratio of two independent random variables each having a χ^2 distribution, divided by their respective degrees of freedom. The form of the density is that of a beta density with $p = \nu_1/2$ and $q = \nu_2/2$, where ν_1 and ν_2 are, respectively, the degrees of freedom of the numerator and denominator χ^2 variables. Fisher's F density is used to assess the equality of variances in, for example, the F -test and the analysis of variance (see **Parametric Tests**).

Weibull distribution

Named after the Swedish Professor Waloddi Weibull, the class of Weibull distributions is sometimes thought of as a generalization of the exponential distribution (which it includes as a special case). The PDF is

$$f(x) = \frac{c}{b} \left(\frac{x-a}{b}\right)^{c-1} \exp\left\{-\left[\frac{(x-a)}{b}\right]^c\right\}, x > a \quad (15)$$

The parameters a and b are location and scale parameters (a is sometimes called the *threshold*, and is often assumed to be 0), while c is a shape parameter. For $a = 0$ and $c = 1$ we obtain the density of the exponential distribution. Weibull distributions are used often in lifetime and time-to-failure models.

Lognormal distribution

If for some value of a , $\ln(X - a)$ has a **normal distribution** with mean μ and variance σ^2 , then X has a lognormal distribution with parameters a , μ and σ . Reparameterizing as $b = \exp(\mu)$, a , b , and c are location, scale, and shape parameters. The PDF is

$$f(x) = \frac{1}{\sigma(x-a)\sqrt{2\pi}} \exp\left[-\frac{1}{2\sigma^2} \left\{\log\left(\frac{x-a}{b}\right)\right\}^2\right],$$

$$x > a \quad (16)$$

The mean and variance are $E(X) = a + b \exp(\sigma^2/2)$ and $Var(X) = b^2 \exp(\sigma^2)[\exp(\sigma^2) - 1]$. The lognormal distribution is a possible model for variables that have a skewed distribution.

Multivariate Density Functions

Multivariate density functions play the same role for *vector random variables* as the density functions described earlier play in the univariate situation. Here we shall look at two such density functions, the multinomial and the multivariate normal.

Multinomial

The multinomial PDF is a multivariate generalization of the binomial density function described earlier. The density function is associated with a vector of random variables $X' = [X_1, X_2, \dots, X_k]$ which arises from a sequence of n independent and identical trials each of which can result in one of k possible mutually exclusive and collectively exhaustive

events, with probabilities $p_1, p_2, \dots, p_k$. The density function is defined as follows:

$$P(X_1 = x_1, X_2 = x_2, \dots, X_k = x_k) = \frac{n!}{x_1! x_2! \dots x_k!} p_1^{x_1} p_2^{x_2} \dots p_k^{x_k} \quad (17)$$

where x_i is the number of trials with outcome i . The expected value of X_i is np_i and its variance is $np_i(1 - p_i)$. The **covariance** of X_i and X_j is $-np_i p_j$.

Multivariate Normal

The PDF of a vector of continuous random variables, $\mathbf{X}' = [X_1, X_2, \dots, X_p]$ defined as follows

$$f(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_p) = (2\pi)^{-p/2} |\Sigma| \times \exp \left[-\frac{1}{2} (\mathbf{x} - \boldsymbol{\mu})' \Sigma^{-1} (\mathbf{x} - \boldsymbol{\mu}) \right] \quad (18)$$

where $\boldsymbol{\mu}$ is the mean vector of the variables and Σ is their covariance matrix.

The simplest version of the multivariate normal density function is that for two random variables and known as the *bivariate normal density function*. The density function formula given above now reduces to

$$f(x_1, x_2) = \frac{1}{2\pi\sigma_1\sigma_2\sqrt{1-\rho^2}} \exp \left\{ -\frac{1}{1-\rho^2} \times \left[\frac{(x_1 - \mu_1)^2}{\sigma_1^2} - 2\rho \frac{(x_1 - \mu_1)}{\sigma_1} \times \frac{(x_2 - \mu_2)}{\sigma_2} + \frac{(x_2 - \mu_2)^2}{\sigma_2^2} \right] \right\} \quad (19)$$

where $\mu_1, \mu_2, \sigma_1, \sigma_2, \rho$ are, respectively, the means, standard deviations, and **correlation** of the two variables. Perspective plots of a number of such density functions are shown in Figure 7.

Figure 7 Four bivariate normal density functions with means 5 and standard deviations 1, for variables 1 and 2, and with correlations equal to 0.0, 0.3, 0.6, and 0.9

Collinearity

Collinearity refers to the intercorrelation among independent variables (or predictors). When more than two independent variables are highly correlated, collinearity is termed *multicollinearity*, but the two terms are interchangeable. Two or more independent variables are said to be collinear when they are perfectly correlated (i.e., $r = -1.0$ or $+1.0$). However, researchers also use the term *collinearity* when independent variables are highly, yet not perfectly, correlated (e.g., $r > 0.70$), a case formally termed *near collinearity* [1]. Collinearity is generally expressed as the multiple **correlation** among the set of i independent variables, or R_i .

Perfect collinearity violates the assumption of ordinary least-squares regression that there is no perfect correlation between any set of two independent variables. In the context of *multiple linear regression*, perfect collinearity renders regression weights of the collinear independent variables uninterpretable, and near collinearity results in biased parameter estimates and inflated standard errors associated with the parameter estimates [1].

Collinearity is obvious in multiple regression when the parameter estimates differ in magnitude and, possibly, in direction from their respective bivariate correlations and when the standard errors of the estimates are high. More formally, the *variance*

inflation factor (VIF) and *tolerance* diagnostics can help detect the presence of collinearity. VIF_i , reflecting the level of collinearity among a set of i independent variables, is defined as $1 / (1 - R_i^2)$, where R_i^2 are the squared multiple correlations among the i independent variables (see **Coefficient of Determination (R^2)**). A *VIF* value of 1 indicates no level of collinearity, and values greater than 1 indicate some level of collinearity. Tolerance is defined as $1 - R_i^2$ or $1/VIF$, where values equal to 1 indicate lack of collinearity, and 0 indicates perfect collinearity. Several remedies exist for reducing or eliminating the problems associated with collinearity, including dropping one or more collinear predictors, combining collinear predictors into a single composite, and employing ridge regression or principal components regression analysis (e.g., [2]).

Confidence Intervals

In textbooks, statistical packages, and statistics courses, confidence intervals are somewhat under-represented compared to **hypothesis testing**. A null hypothesis is a precise statement about one or more population parameters from which, given certain assumptions, a probability distribution for a relevant sample statistic can be derived (see **Hypothesis Testing**). As the name implies, a null hypothesis is usually a hypothesis that no real effect is present (two populations have identical means, two variables are not related in the population, etc.). A decision is made to reject or not reject such a null hypothesis on the basis of a significance test applied to appropriately collected sample data. A significant result is taken to mean that the observed data are not consistent with the null hypothesis, and that a real effect is present. The **significance level** represents the conditional probability that the process would lead to the rejection of the null hypothesis given that it is, in fact, true.

Critics have argued that rejecting or not rejecting a null hypothesis of, say, no difference in population means, does not constitute a full analysis of the data or advance knowledge very far. They have implored researchers to report other aspects of their data such as the size of any observed effects. In particular, they have advised researchers to calculate and report confidence intervals for effects of interest [1, 2]. However, it would be a mistake to believe that relying more on confidence intervals would make significance tests redundant. Confidence intervals can be viewed as a generalization of the null hypothesis significance test, but in order to understand this, the definition of a null hypothesis has to be broadened somewhat. It is, in fact, possible for a null hypothesis to specify an effect size other than zero, and such a hypothesis can be subjected to significance testing provided it allows the derivation of a relevant sampling distribution. To distinguish such null hypotheses from the more familiar null hypothesis of no effect, the term *nil hypothesis* was introduced for the latter [3]. While the significance test of the nil hypothesis indicates whether the data are consistent with a hypothesis that says there is no effect (or an effect of zero size), a confidence interval indicates all those effect sizes with which the data are and are not consistent.

The construction of a confidence interval will be introduced by considering the **estimation** of the mean of a normal population of unknown variance from the information contained in a simple random sample from that population. The formula for the confidence interval is a simple rearrangement of that of the single sample *t* test (see **Parametric Tests**):

$$\bar{X} + t_{0.025, n-1} \left(\frac{\hat{s}}{\sqrt{n}} \right) \leq \mu \leq \bar{X} + t_{0.975, n-1} \left(\frac{\hat{s}}{\sqrt{n}} \right) \quad (1)$$

where $\bar{X}$ is the sample mean, $\hat{s}$ is the unbiased sample standard deviation, n is the **sample size**, $(\hat{s}/\sqrt{n})$ is an estimate of the **standard error** of the mean, and $t_{0.025, n-1}$ and $t_{0.975, n-1}$ are the critical values of t with $n - 1$ **degrees of freedom** that cut off the bottom and top 2.5% of the distribution, respectively. This is the formula for a 95% confidence interval for the population mean of a **normal distribution** whose standard deviation is unknown. In repeated applications of the formula to simple random samples from normal populations, the constructed interval will contain the true population mean on 95% of occasions, and not contain it on 5% of occasions. Intervals for other levels of confidence are easily produced by substituting appropriate critical values. For example, if a 99% confidence interval was required, $t_{0.005, n-1}$ and $t_{0.995, n-1}$ would be employed.

The following example will serve to illustrate the calculation. A sample of 20 products was drawn at random from a manufacturing process and a quality measurement was applied to each. The sample mean was 283.09 and the unbiased sample standard deviation was 51.42. Assuming a normal distribution, the appropriate critical values of t with 19 degrees of freedom are -2.093 and $+2.093$. Substituting in equation (1), gives the 95% confidence interval for the mean of the population as $259.02 \leq \mu \leq 307.16$. It will be clear from the formula that the computed interval is centered on the sample mean and extends a number of estimated standard errors above and below that value. As sample size increases, the exact number of estimated standard errors above and below the mean approaches 1.96 as the t distribution approaches the standardized normal distribution. Of course, as sample size increases, the estimated standard error of the mean decreases and the confidence interval gets

2 Confidence Intervals

narrower, reflecting the greater accuracy of estimation resulting from a larger sample.

The Coverage Interpretation of Confidence Intervals

Ninety five percent of intervals calculated in the above way will contain the appropriate population mean, and 5% will not. This property is referred to as *coverage* and it is a property of the procedure rather than that of a particular interval. When it is claimed that an interval contains the estimated population mean with 95% confidence, what should be understood is that the procedure used to produce the interval will give 95% coverage in the long run. However, for any particular interval that has been calculated, it will be either one of the 95% that contain the population mean or one of the 5% that do not. There is no way of knowing which of these two is true. According to the frequentist view of probability from which the method derives [4], for any particular confidence interval the population is either included or not included in it. The probability of inclusion is therefore either 1 or 0. The confidence interval approach does not give the probability that the true population mean will be in the particular interval constructed, and the term *confidence* rather than *probability* is employed to reinforce the distinction. Despite the claims of the authors of many elementary textbooks [5], significance tests do not result in statements about the probability of the truth of a hypothesis, and confidence intervals, which derive from the same statistical theory, cannot do so either. The relationship between confidence intervals and significance testing is examined in the next section.

The Significance Test Interpretation of Confidence Intervals

The lower limit of the 95% confidence interval calculated above is 259.02. If the sample data were used to conduct a two-tailed, one-sample t test at the 0.05 significance level to test the null hypothesis that the true population mean was equal to 259.02, it would yield a t value that was just non-significant. However, any null hypothesis that specified that the population mean was a value less than 259.02 would be rejected by a test carried out

on the sample data. The situation is similar with the upper limit of the calculated interval, 307.16. The term *plausible* has been applied to values of a population parameter that are included in a confidence interval [6, 7]. According to this usage, the 95% confidence interval calculated above showed any value between 259.02 and 307.16 to be a “plausible” value for the mean of the population, as such values would not be rejected by a two-tailed test at the 0.05 level carried out on the obtained sample data.

One-Sided Confidence Intervals

In some circumstances, interest is focused on estimating only the highest (or lowest) plausible value for a population parameter. The distinction between two-sided intervals and one-sided intervals mirrors that between two-tailed and one-tailed significance tests. The formula for one of the one-sided 95% confidence intervals for the population mean, derived from the one-tailed single sample t test is as follows:

$$-\infty \leq \mu \leq \bar{X} + t_{0.950, n-1} \left(\frac{\hat{s}}{\sqrt{n}} \right) \quad (2)$$

Applying equation (2) to the example data above yields:

$$-\infty \leq \mu \leq 302.97 \quad (3)$$

In the long run, intervals calculated in this way will contain the true population value for 95% of appropriately collected samples.

Central and Noncentral Confidence Intervals

The two-sided and one-sided 95% confidence intervals calculated above represent the extremes of a continuum. With the two-sided interval, the 5% rejection region of the significance test was split equally between the two tails giving limits of 259.02 and 307.16. In the long run, such intervals are exactly as likely to miss the true population mean by having a lower bound that is too high as by having an upper bound that is too low. Intervals with this property are known as *central*. However, with the one-sided interval, which ranged from $-\infty$ to 302.97, it is impossible for the interval to lie above the population mean, but in the long run 5% of such intervals

will fall below the population mean. This is the most extreme case of a noncentral interval.

It is possible to divide the 5% rejection region in an infinite number of ways between the two tails. All that is required is that the tails sum to 0.05. If the lower rejection region was made to be 1% and the upper region made to be 4% by employing $t_{0.010, n-1}$ and $t_{0.960, n-1}$ as the critical values, then 95% of intervals calculated in this way would include the true population mean and 5% would not. Such intervals would be four times more likely to miss the population mean by being too low than by being too high.

While arguments for employing noncentral confidence intervals have been put forward in other disciplines [8], central confidence intervals are usually employed in industrial statistics. In a number of important applications, such as the construction of confidence intervals for population means (and their differences), central confidence intervals have the advantage that they are shorter than noncentral intervals and therefore give the required level of confidence for the shortest range of plausible values.

The Confidence Interval for the Difference between Two Population Means

If the intention is to compare means, then the appropriate approach is to construct a confidence interval for the difference in population means using a rearrangement of the formula for the two independent samples t tests (see **Parametric Tests**):

$$\begin{aligned}
 & (\bar{X}_1 - \bar{X}_2) \pm t_{0.025, n_1 + n_2 - 2} \\
 & \times \sqrt{\left(\frac{(n_1 - 1)\hat{s}_1^2 + (n_2 - 1)\hat{s}_2^2}{n_1 + n_2 - 2} \right) \left(\frac{1}{n_1} + \frac{1}{n_2} \right)} \\
 & \leq \mu_1 - \mu_2 \leq (\bar{X}_1 - \bar{X}_2) \pm t_{0.975, n_1 + n_2 - 2} \\
 & \times \sqrt{\left(\frac{(n_1 - 1)\hat{s}_1^2 + (n_2 - 1)\hat{s}_2^2}{n_1 + n_2 - 2} \right) \left(\frac{1}{n_1} + \frac{1}{n_2} \right)} \quad (4)
 \end{aligned}$$

where $\bar{X}_1$ and $\bar{X}_2$ are the two sample means, $\hat{s}_1$ and $\hat{s}_2$ are the unbiased sample standard deviations, and n_1 and n_2 are the two sample sizes. This is the formula for the 95% confidence interval for the difference between the means of two normal populations, which are assumed to have the

same (unknown) variance. When applied to data from two appropriately collected samples, over the course of repeated application, the upper and lower limits of the interval will contain the true difference in population means for 95% of those applications. The formula is for a central confidence interval that is equally likely to underestimate as it is to overestimate, the true difference in population means. Since the sampling distribution involved is symmetrical, this is the shortest interval providing 95% confidence.

If equation (4) is applied to the sample data that were introduced previously ($\bar{X}_1 = 283.09$, $\hat{s}_1 = 51.42$, and $n_1 = 20$) and to a second sample ($\bar{X}_2 = 328.40$, $\hat{s}_2 = 51.90$, and $n_2 = 21$), the 95% confidence interval for the difference in the two population means ranges from -77.96 to -12.66 (which is symmetrical about the observed difference between the sample means of -45.31). Since this interval does not contain zero, the difference in population means specified by the nil null hypothesis, it is readily apparent that the nil null hypothesis can be rejected at the 0.05 significance level. Therefore, the confidence interval provides all the information provided by a two-tailed test of the nil null hypothesis at the corresponding conventional significance level.

In addition, the confidence interval implies that a two-tailed independent samples t test carried out on the observed data would not lead to the rejection of any null hypothesis that specified the difference in population means was equal to a value in the calculated interval, at the 0.05 significance level. This information is not provided by the usual test of the nil null hypothesis, but is a unique contribution of the confidence interval approach. However, the test of the nil null hypothesis of no population mean difference yields an exact P value for the above samples of 0.008. So the nil null hypothesis can be rejected at a stricter significance level than the 0.05 implied by the 95% confidence interval. So while the confidence interval approach provides a test of all possible null hypotheses at a single conventional significance level, the significance testing approach provides a more detailed evaluation of the extent to which the data cast doubt on just one of these null hypotheses.

If, as in this example, all the “plausible” values for the difference in the means of two populations are of the same sign, then Tukey [9] suggests that it is appropriate to talk of a “confident direction” for

the effect. Here, the 95% confidence interval shows that the confident direction of the effect is that the first population mean is less than the second.

The Confidence Interval for the Difference between Two Population Means and Confidence Intervals for the Two Individual Population Means

The 95% confidence interval for the mean of the population from which the first sample was drawn has been previously shown to range from 259.03 to 307.16. The second sample yields a 95% confidence interval ranging from 304.77 to 352.02. Values between 304.77 and 307.16 are common to both intervals and therefore “plausible” values for the means of both populations. The overlap of the two intervals would be visually apparent if the intervals were presented graphically, and the viewer might be tempted to interpret the overlap as demonstrating the absence of a significant difference between the means of the two samples. However, the confidence interval for the difference between the population means did not contain zero, so the two sample means do differ significantly at the 0.05 level. This example serves to illustrate that caution is required in the comparison and interpretation of two or more confidence intervals. Confidence intervals and significance tests derived from the data from single samples are often based on different assumptions from those derived from the data from two (or more) samples. The former, then, cannot be used to determine the results of the latter directly.

Confidence Intervals Based on Approximations to a Normal Distribution

As sample sizes increase, the sampling distributions of many statistics tend toward a normal distribution with a standard error that is estimated with increasing precision. This is true, for example, of the mean of a random sample from some unknown nonnormal population, where an interval extending from 1.96 estimated standard errors below the observed sample mean to the same distance above the sample mean gives coverage closer and closer to 95% as sample size increases. A rough and ready 95% confidence interval in such cases would range from two

estimated standard errors below the sample statistic to two above. Intervals ranging from one estimated standard error below the sample statistic to one above would give approximately 68% coverage. Confidence intervals for population **correlation** coefficients are often calculated in this way, as Fisher’s z transformation of the sample Pearson correlation (r) tends toward a normal distribution of known variance as sample size increases. The procedure leads to intervals that are symmetrical about the transformed sample correlation (z_r), but the symmetry is lost when the limits of the interval are transformed back to r .

These are large sample approximations, however, and some caution is required in their interpretation. The use of the normal approximation to the binomial distribution in the construction of a confidence interval for a population proportion will be used to illustrate some of the issues.

Constructing Confidence Intervals for the Population Proportion

Under repeated random sampling from a population where the population proportion is π , the sample proportion, p , follows a discrete, binomial distribution (*see Probability Density Functions*), with mean π and standard deviation $\sqrt{\pi(1-\pi)/n}$. As n increases, provided π is not too close to zero or one, the distribution of p tends toward a normal distribution. In these circumstances, $\sqrt{p(1-p)/n}$ can provide a reasonably good estimate of $\sqrt{\pi(1-\pi)/n}$, and an approximate 95% confidence interval for π is provided by

$$p - 1.96\sqrt{\frac{p(1-p)}{n}} \leq \pi \leq p + 1.96\sqrt{\frac{p(1-p)}{n}} \quad (5)$$

In many circumstances, this may provide a serviceable confidence interval. However, the approach uses a continuous distribution to approximate a discrete one and makes no allowance for the fact that $\sqrt{p(1-p)/n}$ cannot be expected to be exactly equal to $\sqrt{\pi(1-\pi)/n}$. Particular applications of this approximation can result in intervals with an impossible limit (less than zero or greater than one) or of zero width (when p is zero or one).

A more satisfactory approach to the question of constructing a confidence interval for a population

proportion, particularly when the sample size is small, is to return to the relationship between the plausible parameters included in a confidence interval and statistical significance. According to this, the lower limit of the 95% confidence interval should be that value of the population proportion, π_L , which if treated as the null hypothesis, would just fail to be rejected in the upper tail of a two-tailed test at the 0.05 level on the observed data. Similarly, the upper limit of the 95% confidence interval should be that value of the population proportion, π_U , which if treated as the null hypothesis, would just fail to be rejected in the lower tail of a two-tailed test at the 0.05 level on the observed data. However, there are particular problems in conducting two-tailed tests on a discrete variable like the sample proportion [10]. As a result, the approach taken is to work in terms of one-tailed tests and to find the value of the population proportion π_L , which if treated as the null hypothesis, would just fail to be rejected by a one-tailed test (in the upper tail) at the 0.025 level on the observed data, and the value π_U , which if treated as the null hypothesis, would just fail to be rejected by a one-tailed test (in the lower tail) at the 0.025 level on the observed data [11].

The approach will be illustrated with a small sample example that leads to obvious inconsistencies when the normal approximation is applied. A simple random sample of products is drawn from a manufacturing process. Of the 20 products in the sample, two are defective, while 18 are free from defects. The task is to construct a 95% confidence interval for the proportion of products that is free from defects.

Using the normal approximation method, equation (5) would yield:

$$0.9 - 1.96\sqrt{\frac{0.9(1-0.9)}{20}} \leq \pi \leq 0.9 + 1.96\sqrt{\frac{0.9(1-0.9)}{20}} \quad (6)$$

The upper limit of this symmetrical interval is outside the range of the parameter. Even if it was treated as one, it is clear that if this were made the null hypothesis of a one-tailed test at the 0.025 level, then it must be rejected on the basis of the observed data, since if the process delivered 100% defect-free products, the sample could not contain any defective products, but it did contain two.

The exact approach proceeds as follows: That value of the population proportion, π_L , is found such that under this null hypothesis the sum of the probabilities of 18, 19, and 20 defect-free products in the sample of 20 would equal 0.025. Reference to an appropriate table [12] or statistical package (e.g., Minitab) yields a value of 0.683017. Then, that value of the population proportion, π_U , is found such that under this null hypothesis the sum of the probabilities of 0, 1, 2, ..., 18 defect-free products in a sample of 20 would be 0.025. The desired value is 0.987651.

So the exact 95% confidence interval for the population proportion of products is

$$0.683017 \leq \pi \leq 0.987651 \quad (7)$$

If a one-tailed test at the 0.025 level was conducted on any null hypothesis that specified that the population proportion was less than 0.683017, it would be rejected on the basis of the observed data. So also would any null hypothesis that specified that the population proportion was greater than 0.987651.

In contrast to the limits indicated by the approximate method, those produced by the exact method will always lie within the range of the parameter and will not be symmetrical around the sample proportion (except when this is exactly 0.5). The exact method yields intervals that are conservative in coverage [13, 14], and alternatives have been suggested. One approach questions whether it is appropriate to include the full probability of the observed outcome in the tail when computing π_L and π_U . Berry and Armitage [11] favor mid-P confidence intervals where only half the probability of the observed outcome is included. The Mid-P intervals will be rather narrower than the exact intervals, and will result in a rather less conservative coverage. However, in some circumstances the Mid-P coverage can fall below the intended level of confidence, which cannot occur with the exact method [14].

Confidence Intervals and the Bootstrap

While the central limit theorem might provide support for the use of the normal distribution in constructing approximate confidence intervals in some situations, there are other situations where sample sizes are too small to justify the process, or sampling distributions

are suspected or known to depart from normality. The **bootstrap** (“Overview of **resampling**, (*see* **Bootstrap and Jackknife, Overview**) bootstrapping and jackknifing” in the CIM section (has no id. yet)) [6, 15] is a numerical method designed to derive some idea of the sampling distribution of a statistic without recourse to assumptions of unknown or doubtful validity. The approach is to treat the collected sample of data as if it were the population of interest. A large number of random samples are drawn with replacement from this “population”, each sample being of the same size as the original sample. The statistic of interest is calculated for each of these “resamples” and an empirical sampling distribution is produced. If a large enough number of resamplings is performed, then a 95% confidence interval can be produced directly from these by identifying those values of the statistic that correspond to the 2.5th and 97.5th **percentiles**. On other occasions, the standard deviation of the statistic over the “resamples” is calculated and this is used as an estimate of the true standard error of the statistic in one of the standard formulas. Various ways of improving the process have been developed and subjected to some empirical testing. With small samples or with samples that just by chance are not very representative of their parent population, the method may provide rather unreliable information. Nonetheless, Efron and Tibshirani [6] provide evidence that it works well in many situations, and the methodology is becoming increasingly popular.

Bayesian Certainty Intervals

Confidence intervals derive from the frequentist approach to statistical inference that defines probabilities as the limits in the long run of relative frequencies. According to this view, the confidence interval is the random variable, not the population parameter [4, 8]. In consequence, when a 95% confidence interval is constructed, the frequentist position does not allow statements of the kind “The value of the population parameter lies in this interval with probability 0.95.” In contrast, the Bayesian approach to statistical inference (*see* **Probability Theory**) defines probability as a subjective or psychological variable [16]. According to this view, it is not only acceptable to claim that particular probabilities are associated with particular values of a parameter; such claims are the

very basis of the inference process. Bayesians use Bayes theorem to update their prior beliefs about the probability distribution of a parameter on the basis of new information. Sometimes, this updating process uses elements of the same statistical theory that is employed by a frequentist and the final result may appear to be identical to a confidence interval. However, the interpretation placed on the resulting interval could hardly be more different.

Suppose that a Bayesian was interested in estimating the mean score of some population on a particular measurement scale. The first part of the process would involve attempting to sketch a prior probability distribution for the population mean, showing what value seemed most probable, whether the distribution was symmetrical about this value, how spread out the distribution was, perhaps trying to specify the parameter values that contained the middle 50% of the distribution, the middle 90%, and so on. This process would result in a subjective prior distribution for the population mean. The Bayesian would then collect sample data, in very much the same way as a frequentist, and use Bayes theorem to combine the information from this sample with the information contained in the prior distribution to compute a posterior probability distribution. If the 2.5th and 97.5th percentiles of this posterior probability distribution are located, they form the lower and upper bounds on the Bayesian’s 95% certainty interval [16].

Certain parallels and distinctions can be drawn between the confidence interval of the frequentist and the certainty interval of the Bayesian. The center of the frequentist’s confidence interval would be the sample mean, but the center of the Bayesian’s certainty interval would be somewhere between the sample mean and the mean of the prior distribution. The smaller the variance of the prior distribution, the nearer the center of the certainty interval will be to that of the prior distribution. The width of the frequentist’s confidence interval would depend only on the sample standard deviation and the sample size, but the width of the Bayesian’s certainty interval would be narrower, as the prior distribution contributes a “virtual” sample size that can be combined with the actual sample size, to yield a smaller posterior estimate of the standard error as well as contribute to the degrees of freedom of any required critical values.

So, to the extent that the Bayesian had any views about the likely values of the population mean before

data were collected, these views will influence the location and width of the 95% certainty interval. Any interval so constructed is to be interpreted as a probability distribution for the population mean, permitting the Bayesian to make statements like, "The probability that μ lies between L and U is X." Of course, none of this is legitimate to the frequentist who distrusts the subjectivity of the Bayesian's prior distribution, its influence on the resulting interval, and the attribution of a probability distribution to a population parameter that can only have one value.

If the Bayesian admits ignorance of the parameter being estimated prior to the collection of the sample, then a uniform prior might be specified which says that any and all values of the population parameter are equally likely. In these circumstances, the certainty interval of the Bayesian and the confidence interval of the frequentist will be identical in numerical terms. However, an unbridgeable gulf will still exist between the interpretations that would be made of the interval.

Estimation

Introduction

In the simplest case, a data set consists of observations on a single variable, say real-valued observations. Suppose there are n such observations, denoted by $X_1, \dots, X_n$. For example, X_i could be a quality characteristic of product i , or the number of car accidents on day i , and so on. Suppose now that each observation follows the same probability law P . This means that the observations are relevant if one wants to predict the value of a new observation X (say, the quality of a new product, or the number of car accidents on a future day, etc.). Thus, a common underlying distribution P allows one to generalize the outcomes.

The emphasis in this paper is on the data and estimators derived from the data, and less on the estimation of population parameters describing a model for P . An estimator is any given function $T_n(X_1, \dots, X_n)$ of the data. Let us start with reviewing some common estimators.

The Empirical Distribution

The unknown P can be estimated from the data in the following way. Suppose first that we are interested in the probability that an observation falls in A , where A is a certain set chosen by the researcher. We denote this probability by $P(A)$. Now, from the frequentist point of view, a probability of an event is the limit of relative frequencies of occurrences of that event as the number of occasions of possible occurrences n grows without limit. So, it is natural to estimate $P(A)$ by the frequency of A that is, by

$$\begin{aligned} \hat{P}_n(A) &= \frac{\text{number of times an observation } X_i \text{ falls in } A}{\text{total number of observations}} \\ &= \frac{\text{number of } X_i \in A}{n} \end{aligned} \quad (1)$$

We now define the empirical distribution $\hat{P}_n$ as the probability law that assigns to a set A the probability $\hat{P}_n(A)$. We regard $\hat{P}_n$ as an estimator of the unknown P .

The Empirical Distribution Function

The distribution function of X is defined as

$$F(x) = P(X \leq x) \quad (2)$$

and the empirical distribution function is

$$\hat{F}_n(x) = \frac{\text{number of } X_i \leq x}{n} \quad (3)$$

Figure 1 plots the distribution function $F(x) = 1 - 1/x^2$, $x \geq 1$ (smooth curve) and the empirical distribution function $\hat{F}_n$ (stair function) of a sample from F with **sample size** $n = 200$.

Sample Moments and Sample Variance

The theoretical mean

$$\mu = E(X) \quad (4)$$

(E stands for *Expectation*), can be estimated by the sample average

$$\bar{X}_n = \frac{X_1 + \dots + X_n}{n} \quad (5)$$

Generally, for $j = 1, 2, \dots$ the j th sample moment

$$\hat{\mu}_{j,n} = \frac{X_1^j + \dots + X_n^j}{n} \quad (6)$$

Figure 1 The empirical and theoretical distribution function

2 Estimation

is an estimator of the j th moment $E(X^j)$ of P (see **Moments**).

The sample variance

$$S_n^2 = \frac{1}{n-1} \sum_{i=1}^n (X_i - \bar{X}_n)^2 \quad (7)$$

is an estimator of the variance $\sigma^2 = E(X - \mu)^2$.

Sample Median

The median of X is the value m that satisfies $F(m) = 1/2$ (assuming there is a unique solution). Its empirical version is any value $\hat{m}_n$ such that $\hat{F}_n(\hat{m}_n)$ is equal or as close as possible to $1/2$. In the above example $F(x) = 1 - 1/x^2$, so that the theoretical median is $m = \sqrt{2} = 1.4142$. In the ordered sample, the 100th observation is equal to 1.4166, and the 101th observation is equal to 1.4191. A common choice for the sample median is taking the average of these two values. This gives $\hat{m}_n = 1.4179$.

Parametric Models

The distribution P may be partly known beforehand. The unknown parts of P are called *parameters* of the model. For example, if the X_i are the results of pass/fail inspection on products (the binary case), we know that P allows only two possibilities, say 1 and 0 (pass = 1, fail = 0). There is only one parameter, the probability that the product passes $\theta = P(X = 1)$. Generally, in a parametric model, it is assumed that P is known up to a finite number of parameters $\theta = (\theta_1, \dots, \theta_d)$. We then write $P = P_\theta$. When there are infinitely many parameters (e.g., the case when P is completely unknown), the model is called *nonparametric*.

If $P = P_\theta$ is a parametric model, one can often apply the maximum-likelihood procedure to estimate θ (see **Maximum Likelihood**).

Example 1 The time one stands in line for a certain service is often modeled as exponentially distributed (see **Probability Density Functions**). The random variable X representing the waiting time then has a density of the form

$$f_\theta(x) = \theta e^{-\theta x}, \quad x > 0 \quad (8)$$

where the parameter θ is the so-called *intensity* (a large value of θ means that – on average – the waiting time is short), and the maximum-likelihood estimator of θ is

$$\hat{\theta}_n = \frac{1}{\bar{X}_n} \quad (9)$$

Example 2 In many cases, one assumes that X is normally distributed (see **Probability Density Functions; Normal Distribution**). In that case there are two parameters: the mean $\theta_1 = \mu$ and the variance $\theta_2 = \sigma^2$. The maximum-likelihood estimators of (μ, σ^2) are $(\hat{\mu}_n, \hat{\sigma}_n^2)$, where $\hat{\mu}_n = \bar{X}_n$ is the sample mean and $\hat{\sigma}_n^2 = \sum_{i=1}^n (X_i - \bar{X}_n)^2/n$.

The Method of Moments

Suppose that the parameter θ can be written as a given function of the **moments** $\mu_1, \mu_2, \dots$. The *method of moments estimator* replaces these moments by their empirical counterparts $\hat{\mu}_{n,1}, \hat{\mu}_{n,2}, \dots$.

Example 3 Vilfredo Pareto [1] noticed that the number of people whose income exceeds level x is often approximately proportional to $x^{-\theta}$, where θ is a parameter that differs from country to country. Therefore, as a model for the distribution of incomes, one may propose the Pareto density

$$f_\theta(x) = \frac{\theta}{x^{\theta+1}}, \quad x > 1 \quad (10)$$

When $\theta > 1$, one has $\theta = \mu/(\mu - 1)$. Hence, the method of moments estimator of θ is in this case $t_1(\hat{P}_n) = \bar{X}_n/(\bar{X}_n - 1)$. After some calculations, one finds that the maximum-likelihood estimator of θ is $t_2(\hat{P}_n) = (n / \sum_{i=1}^n \log X_i)$. Let us compare these on the simulated data in Figure 1. We generated in this simulation a sample from the Pareto distribution with $\theta = 2$. The sample average turns out to be $\bar{X}_n = 1.9669$, so that the methods of moments estimate is 2.0342. The maximum-likelihood estimate is 1.9790. Thus, the maximum-likelihood estimate is a little closer to the true θ than the methods of moments estimate.

Besides maximum likelihood and the method of moments, the method of least squares is a common estimation method.

Properties of Estimators

Let $T_n = T_n(X_1, \dots, X_n)$ be an estimator of the real-valued parameter θ . Then it is desirable that T_n is in some sense close to θ . A minimum requirement is that the estimator approaches θ as the sample size increases. This is called *consistency*. To be more precise, suppose the sample $X_1, \dots, X_n$ are the first n of an infinite sequence $X_1, X_2, \dots$ of independent copies of X . Then T_n is called *consistent* if (with probability one)

$$T_n \longrightarrow \theta \text{ as } n \longrightarrow \infty \quad (11)$$

Note that consistency of frequencies as estimators of probabilities, or means as estimators of expectations, follows from the (strong) law of **large numbers**.

The *bias* of an estimator T_n of θ is defined as its mean deviation from θ :

$$\text{bias}(T_n) = E(T_n) - \theta \quad (12)$$

We remark here that the distribution of $T_n = T_n(X_1, \dots, X_n)$ depends on P , and, hence, on θ . Therefore, the expectation $E(T_n)$ depends on θ as well. We indicate this by writing $E(T_n) = E_\theta(T_n)$. The estimator T_n is called *unbiased* if

$$E_\theta(T_n) = \theta \text{ for all possible values of } \theta \quad (13)$$

Example 4 Consider the estimators $S_n^2 = \sum_{i=1}^n (X_i - \bar{X})^2 / (n-1)$ and $\hat{\sigma}_n^2 = \sum_{i=1}^n (X_i - \bar{X})^2 / n$. Note that S_n^2 is larger than $\hat{\sigma}_n^2$, but that the difference is small when n is large. It can be shown that S_n^2 is an unbiased estimator of the variance $\sigma^2 = \text{var}(X)$. The estimator $\hat{\sigma}_n^2$ is biased: it underestimates the variance.

In many models, unbiased estimators do not exist. Moreover, it often heavily depends on the model under consideration, whether or not an estimator is unbiased. A weaker concept is *asymptotic unbiasedness* (see [2]).

The mean square error of T_n as estimator of θ is

$$MSE(T_n) = E(T_n - \theta)^2 \quad (14)$$

One may decompose the MSE as

$$MSE(T_n) = \text{bias}^2(T_n) + \text{var}(T_n) \quad (15)$$

where $\text{var}(T_n)$ is the variance of T_n (whose square root is named the standard error).

Bias, variance, and mean square error are often quite hard to compute, because they depend on the distribution of all n observations $X_1, \dots, X_n$. However, one may use certain approximations for large sample sizes n . Under regularity conditions, the maximum-likelihood estimator $\hat{\theta}_n$ of θ is asymptotically unbiased, with asymptotic variance $1/(nI(\theta))$, where $I(\theta)$ is the Fisher information in a single observation. Thus, maximum-likelihood estimators reach the minimum variance bound asymptotically.

Histograms

Our next aim is estimating the density $f(x)$ at a given point x . The density (see **Probability Density Function (PDF)**) is defined as the derivative of the distribution function F at x :

$$f(x) = \lim_{h \rightarrow 0} \frac{F(x+h) - F(x)}{h} = \lim_{h \rightarrow 0} \frac{P(x, x+h]}{h} \quad (16)$$

Here, $(x, x+h]$ is the interval with left endpoint x (not included) and right endpoint $x+h$ (included). Unfortunately, replacing P by $\hat{P}_n$ here does not work, as for h it is small enough, $\hat{P}_n(x, x+h]$ will be equal to zero. Therefore, instead of taking the limit as $h \rightarrow 0$, we fix h at a (small) positive value, called the *bandwidth*. The estimator of $f(x)$, thus, becomes

$$\hat{f}_n(x) = \frac{\hat{P}_n(x, x+h]}{h} = \frac{\text{number of } X_i \in (x, x+h]}{nh} \quad (17)$$

A plot of this estimator at points $x \in \{x_0, x_0+h, x_0+2h, \dots\}$ is called a *histogram* (see **Graphical Representation of Data**).

Example 3 continued Figure 2 shows the histogram, with bandwidth $h = 0.5$, for the sample of size $n = 200$ from the Pareto distribution with parameter $\theta = 2$. The solid line is the density of this distribution.

Minimum χ^2

Of course, for real (not simulated) data, the underlying distribution/density is not known. Let us explain in an example a procedure for checking whether certain model assumptions are reasonable. Suppose

Figure 2 Histogram with bandwidth $h = 0.5$ and true density

that one wants to test whether data come from the exponential distribution with parameter θ equal to 1. We draw a histogram of the sample (sample size $n = 200$), with bandwidth $h = 1$ and 10 cells (see Figure 3). The cell counts are (151, 28, 4, 6, 1, 1, 4, 3, 1, 1). Thus, for example, the number of observations that falls in the first cell that is, those that have values between 0 and 1, is equal to 151. The cell probabilities are, therefore, (0.755, 0.140, 0.020, 0.030, 0.005, 0.005, 0.020, 0.015, 0.005, 0.005). Now, according to the exponential distribution, the probability that an observation falls in cell k is equal to $e^{-(k-1)} - e^{-k}$, for $k = 1, \dots, 10$. These cell probabilities are (0.6621, 0.2325, 0.0855, 0.0315, 0.0116, 0.0043, 0.0016, 0.0006, 0.0002, 0.0001). Because the probabilities of the last four cells are very small, we merge them together. This gives cell counts $(N_1, \dots, N_7) = (151, 28, 4, 6, 1, 1, 9)$ and cell probabilities $(\pi_1, \dots, \pi_7) = (0.6621, 0.2325, 0.0855, 0.0315, 0.0116, 0.0043, 0.0025)$. To check whether the cell frequencies differ significantly from the hypothesized cell probabilities, we calculate Pearson's χ^2 . It is defined as

$$\chi^2 = \frac{(N_1 - n\pi_1)^2}{n\pi_1} + \dots + \frac{(N_7 - n\pi_7)^2}{n\pi_7} \quad (18)$$

We write this as $\chi^2 = \chi^2(\text{exponential})$ to stress that the cell probabilities were calculated assuming the exponential distribution. Now, if the data are exponentially distributed, the χ^2 statistic is generally not too large. But what is large? Consulting a table of Pearson's χ^2 at the 5% **significance**

level gives the critical value $c = 12.59$. Here we use six **degrees of freedom**. This is because there are $m = 7$ cell probabilities, and there is the restriction $\pi_1 + \dots + \pi_m = 1$, so we estimated $m - 1 = 6$ parameters. After some calculations, one obtains $\chi^2(\text{exponential}) = 168.86$. This exceeds the critical value c , that is, $\chi^2(\text{exponential})$ is too large to support the assumption of the exponential distribution. In fact, the data considered here are the simulated sample from the Pareto distribution with parameter $\theta = 2$. We shifted this sample one unit to the left. The value of χ^2 for this (shifted) Pareto distribution is

$$\chi^2(\text{Pareto}) = 10.81 \quad (19)$$

This is below the critical value c , so that the test, indeed, does not reject the Pareto distribution. However, this comparison is not completely fair, as our decision to merge the last four cells was based on the exponential distribution, which has much lighter tails than the Pareto distribution.

In Figure 3, the histogram is shown, together with the densities of the exponential and Pareto distribution. Indeed, the Pareto distribution fits the data better in the sense that it puts more mass at small values.

Continuing with the test for the exponential distribution, we note that, in many situations, the intensity θ is not required to be fixed beforehand. One may use an estimator for θ and proceed as before, calculating χ^2 with the estimated value for θ . However, the critical values of the test then become smaller.

Figure 3 Histogram with bandwidth $h = 1$, exponential and Pareto density

This is because, clearly, estimating parameters using the sample means that the hypothesized distribution is pulled toward the sample. Moreover, when using, for example, maximum-likelihood estimators of the parameters, critical values will in fact be hard to compute. The minimum χ^2 estimator overcomes this problem. Let $\pi_k(\vartheta)$ denote the cell probabilities when the parameter value is ϑ , that is, in the exponential case $\pi_k(\vartheta) = e^{-\vartheta(k-1)} - e^{-\vartheta k}$, $k = 1, \dots, m-1$, and $\pi_m(\vartheta) = 1 - \sum_{k=1}^{m-1} \pi_k(\vartheta)$. The minimum χ^2 estimator $\hat{\theta}_n$ is now the minimizer over ϑ of

$$\left\{ \frac{(N_1 - n\pi_1(\vartheta))^2}{n\pi_1(\vartheta)} + \dots + \frac{(N_m - n\pi_m(\vartheta))^2}{n\pi_m(\vartheta)} \right\} \quad (20)$$

The χ^2 test with this estimator for θ now has $m-2$ degrees of freedom. Generally, the number of degrees of freedom is $m-1-d$, where d is the number of estimated free parameters when calculating cell probabilities. The critical values of the test can be found in a χ^2 table.

Sufficiency

A goal of statistical analysis is generally to summarize the (large) data set into a small number of characteristics. The sample mean and sample variance are such summarizing statistics, but so is, for example, the sample median, and so on. The question arises, to what extent one can summarize data without throwing away information. For example, suppose you are given the empirical distribution function $\hat{F}_n$, and you are asked to reconstruct the original data $X_1, \dots, X_n$. This is not possible since the ordering of the data is lost. However, the index i of X_i is just a label: it contains no information about the distribution P of X_i (assuming that each observation X_i comes from the same distribution, and the observations are independent). We say that the empirical distribution $\hat{F}_n$ is *sufficient*. Generally, a statistic

$T_n = T_n(X_1, \dots, X_n)$ is called *sufficient* for P if the distribution of the data given the value of T_n does not depend on P . For example, it can be shown that when P is the exponential distribution with unknown intensity, then the sample mean is sufficient. When P is the **normal distribution** with unknown mean and variance, then the sample mean and sample variance are sufficient. Cell counts are not sufficient when, for example, P is a continuous distribution. This is because, if one only considers the cell counts, one throws away information on the distribution within a cell. Indeed, when one compares Figures 2 and 3 (recall that in Figure 3 we shifted the sample one unit to the left), one sees that, by using just 10 cells instead of 20, the strong decrease in the second half of the first cell is no longer visible.

Sufficiency depends very heavily on the model for P . Clearly, when one decides to ignore information because of a sufficiency argument, one may be ignoring evidence that the model's assumptions may be wrong. Sufficiency arguments should be treated with caution.

Expectation

The expectation or expected value of a random variable is also referred to as its *mean* or *average value*. The terms *expectation*, *expected value*, and *mean* can be used interchangeably. The expectation can be thought of as a measure of the “center” or “location” of the probability distribution of the random variable. Two other measures of the center or location are the median and the mode. If the random variable is denoted by the letter X , the expectation of X is usually denoted by $E(X)$, read “ E of X ”.

The form of the definition of the expectation of a random variable is slightly different depending on the nature of the probability distribution of the random variable (see **Probability Density Functions**). The expectation of a discrete random variable is defined as the sum of each value of the random variable weighted by the probability that the random variable is equal to that value. Thus,

$$E(X) = \sum_x xf(x) \quad (1)$$

where $f(x)$ denotes the probability distribution of the discrete random variable, X . So for example, suppose that the random variable X takes on five discrete values, -2 , -1 , 0 , 1 , and 2 . Also suppose that the probability that the random variable takes on the value -2 (i.e., $X = -2$) is equal to 0.1 , and that $P(X = -1) = 0.2$, $P(X = 0) = 0.3$, $P(X = 1) = 0.25$, and $P(X = 2) = 0.15$. Then,

$$E(X) = (-2 \times 0.1) + (-1 \times 0.2) + (0 \times 0.3) + (1 \times 0.25) + (2 \times 0.15) = 0.15 \quad (2)$$

Note that the individual probabilities sum to 1 . The expectation is meant to summarize a “typical” observation of the random variable but, as can be seen from the example above, the expectation of a random variable is not necessarily equal to one of the values of that random variable. It can also be very sensitive to small changes in the probability assigned to a large value of X .

It is possible that the expectation of a random variable does not exist. In the case of a discrete random variable, this occurs when the sum defining the expectation does not converge or is not equal to infinity. Consider the *St. Petersburg paradox* discovered by

the Swiss eighteenth-century mathematician, Daniel Bernoulli [1]. A fair coin is tossed repeatedly until it shows tails. The total number of tosses determines the prize, which equals $\$2^n$, where n is the number of tosses. The expected value of the prize for each toss is $\$1$ ($2 \times 0.5 + 0 \times 0.5$). The expected value of the prize for the game is the sum of the expected values for each toss. As there are an infinite number of tosses, the expected value of the prize for the game is an infinite number of dollars.

The expectation of a continuous random variable is defined as the integral of the individual values of the random variable weighted according to their probability distribution. Thus,

$$E(X) = \int_{-\infty}^{\infty} xf(x) dx \quad (3)$$

where $f(x)$ is the probability distribution (see **Probability Density Function (PDF)**) of the continuous random variable, X . This achieves the same end for a continuous random variable as equation (1) did for a discrete random variable; it sums each value of the random variable weighted by the probability that the random variable is equal to that value.

Again it is possible that the expectation of the continuous random variable does not exist. This occurs when the integral does not converge or equals infinity. A classic example of a random variable whose expected value does not exist is a Cauchy random variable.

An expectation can also be calculated for the function of a random variable. This is done by applying equation (1) or (3) to the distribution of a function of the random variable. For example, a function of the random variable X is $(X - \mu_X)^2$, where μ_X denotes the mean of the random variable X . The expectation of this function is referred to as the *variance* (see **Variance**) of X . The mean and variance are related to the first and second *moment* (see **Moments**).

Expectations have a number of useful properties.

1. The expectation of a constant is equal to that constant.
2. The expectation of a constant multiplied by a random variable is equal to the constant multiplied by the expectation of the random variable.
3. The expectation of the sum of a group of random variables is equal to the sum of their individual expectations.

2 Expectation

4. The expectation of the product of a group of random variables is equal to the product of their individual expectations if the random variables are independent.

More information on the topic of expectation is given in [2–4].

Exploratory Data Analysis

For most statisticians in the late 1960s and early 1970s, the really hot topics in their subject were definitely not simple **descriptive statistics** or basic plots. Instead, the fireworks came from the continuing debates over the nature of statistical inference and the foundations of probability, followed closely by the modeling of increasingly complex experimental designs within a general *analysis of variance* setting, an area that was boosted by the growing availability of cheap and powerful computing facilities. However, in an operation reminiscent of the *samizdat* in the latter days of the Soviet Union (which secretly circulated the banned novels of Aleksandr Solzhenitsyn, among other things), mimeographed copies of a revolutionary recasting of statistics began their hand-to-hand journey around a selected number of universities from early 1970 onward.

This heavily thumbed, three-volume text was not the work of a dissident junior researcher impatient with the conservatism of his/her elders, but was by one of America's most distinguished mathematicians, John Tukey. What Tukey did was to reestablish the relationship between these neglected descriptive measures (and plots) and many of the currently active areas in statistics, including computing, modeling, and inference. In doing so, he also resuscitated interest in the development of new summary measures and displays, and in the almost moribund topic of regression. The central notion behind what he termed *exploratory data analysis*, or EDA, is simple but fruitful: knowledge about the world comes from many wells and by many routes. One legitimate and productive way is to treat data not as being merely supportive of already existing knowledge, but primarily as a source of new ideas and hypotheses. For Tukey, like a detective looking for the criminal, the world was full of potentially valuable material that could yield new insights into what might be the case. EDA is the active reworking of this material with the aim of extracting new meanings from it: "The greatest value of a picture is when it *forces* us to notice what we never expected to see" [6, p. vi]. In addition, while EDA has very little to say about how data might be gathered (although there is a subdivision of the movement whose concentration on model evaluation could be said to have *indirect* implications for **data**

collection), the movement is very concerned that the tools to extract meaning from data do so with minimum ambiguity. What this indicates, using a slightly more technical term, is that EDA is concerned with *robustness*, that is, with the study of all the factors that disturb or distort conclusions drawn from data, and how to draw their teeth (see also [1] for an introduction to EDA, which nicely mixes the elementary with the sophisticated aspects of the topic).

A simple example here is the use of the median *versus* the arithmetic mean as a measure of *location*, the former is said to be robust and resistant to discrepant values or *outliers* because it is based only on the *position* of the middle number in the (ordered) sample, while the latter uses all the numbers and their values, however unrepresentative, in its calculation. Further, a *trimmed mean*, calculated from an *ordered* sample where, say, 10% of the top and bottom numbers have been removed, is also more robust and resistant than the raw arithmetic mean based on all the readings, since trimming automatically removes any outliers, which by definition, lie in the upper and lower tails of such a sample, and are few in number. In general, robust-resistant measures are preferable to nonrobust ones because, while both give pretty much the same answer in samples where there are no outliers, the former yields a less distorted measure in samples where outliers are present. Tukey and some of his colleagues [2] set themselves the task of investigating over 35 separate measures of location for their robustness. Although the median and the percentage trimmed mean came out well, Tukey also promoted the computer-dependent *biweight* as his preferred measure of location. Comparable arguments can also be made for choosing a robust measure of *spread* (or *scale*) over a nonrobust one, with the *midspread* (or interquartile range), that is, the middle 50% of a sample (or the difference between the upper and lower quartiles (see **Quartiles**) or *hinges*, to use Tukey's term), being more acceptable than the variance or the standard deviation. Since the experienced data explorer is unlikely to know beforehand what to expect with a given *batch* (Tukey's neologism for a *sample*), descriptive tools that are able to cope with messy data sets are preferable to the usual, but more outlier-prone, alternatives.

Plots that use robust rather than outlier-sensitive measures have also been part of the EDA doctrine; thus the ubiquitous box-and-whisker plot is based on both the median and the midspread, while the latter

measure helps determine the whisker length, which can then be useful in identifying potential outliers. Similar novelties such as the stem and leaf plot are also designed for the median rather than the mean to be read off easily, as can the upper and lower quartiles, and hence the midspread. Rather more exotic birds such as *hanging or suspended rootograms* and *half-normal plots* (all used for checking the Gaussian nature of the data) were either Tukey's own creation or that of workers influenced by him, for instance, Daniel and Wood [3], whose classic study of data modeling owed much to EDA. Tukey did not neglect earlier and simpler displays such as scatterplots (*see Graphical Representation of Data*), although, true to his radical program, these became transformed into windows to data shape and symmetry, robustness, and even robust differences of location and spread. A subset of these displays, residual and leverage plots for instance, also played a key role in the revival of interest in regression, particularly in the area termed *regression diagnostics*. In addition, while EDA has concentrated on relatively simple data sets and data structures, there are less well known but still provocative incursions into the partitioning of multiway and multifactor tables [4], including Tukey's rethinking of the analysis of variance (*see* [5]).

While EDA offered a flexibility and adaptability to knowledge building that was missing from the more formal processes of statistical inference, this was achieved with a loss of certainty about the knowledge gained – provided, of course, that one believes that more formal methods do generate truth, or your money back. Tukey was less sure on this latter point in that while formal methods of inference are bolted on to EDA in the form of confirmatory data analysis, or CDA (which favored the Bayesian route – *see* Mosteller and Tukey's early account of EDA and CDA in [6]), he never expended as much effort on CDA as he did on EDA, although he often argued that both should run in harness, with one complementing the other. Thus, for Tukey (and EDA), truth gained by such an epistemologically *inductive* method was always going to be partial, local, and relative, and liable to fundamental challenge and change. On the other hand, without taking such risks, nothing new could emerge. What seemed to be on offer, therefore, was an *entrepreneurial* view of statistics, and *science*, as a permanent revolution.

Although EDA broke cover more than 25 years ago with the simultaneous publication of the two

texts on EDA and regression [7, 8], it is still too early to say what has been the real impact of EDA on data analysis. On the one hand, many of EDA's graphical novelties have been incorporated into most modern texts and computer programs in statistics, as have the raft of robust measures on offer. On the other, the risky approach to statistics adopted by EDA has been less popular, with deduction-based inference taken to be the only way to discover the world. However, while one could point to underlying and often contradictory cultural movements in scientific belief and practice to account for the less than wholehearted embrace of Tukey's ideas, the future of statistics lies with EDA.

Heteroscedasticity

Introduction

Homoscedasticity is the condition in which a random variable or its observed values have the same degree of variation for all sampling units in the mathematical model or data set. By “constant variation” we usually mean a common variance for all sampling units. When that condition is not met, the random variable or data are called *heteroscedastic*. The origin of these terms is from the Greek word $\sigma\kappa\epsilon\delta\acute{\alpha}\nu\nu\mu\iota$, “to scatter or disperse”, and the Greek words for “same” and “different”.

Linear Regression Analysis

Homoscedasticity is an essential assumption in the linear regression model and its fit by *least squares*. For the simplest case of a single dependent variable Y and one independent variable X , the model is

$$Y_i = \alpha + \beta X_i + e_i, \quad i = 1, \dots, N \quad (1)$$

The e_i are random variables with $E(e_i) = 0$, and if the homoscedasticity condition holds, $\text{var}(e_1) = \dots = \text{var}(e_N) = \sigma^2$. If the random disturbance terms are heteroscedastic and have different variances $\sigma_i^2 = \text{var}(e_i)$, the ordinary least-squares estimators of α and β , while still unbiased, no longer have the Gauss–Markov property of minimum variance. If the individual variances are known up to a proportionality constant, weighted least-squares fit of the linear model can be obtained by using the scaled data

$$\frac{Y_i}{\sigma_i} = \frac{\alpha}{\sigma_i} + \frac{\beta X_i}{\sigma_i} + \frac{e_i}{\sigma_i} \quad (2)$$

The usual ordinary least-squares **estimation** process is applied to the scaled values, with the intercept also scaled by the known standard deviations σ_i .

The weighted least-squares estimators are easily displayed by the matrix form of the multiple regression model with an intercept and p independent variables:

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{e} \quad (3)$$

$\mathbf{Y}$ is the $N \times 1$ vector of observations on the dependent variable. $\mathbf{X}$ is the $N \times (p + 1)$ matrix of predictor variable values of full rank $p + 1$, with a

first column of ones for the intercept term. $\boldsymbol{\beta}$ is the $(p + 1) \times 1$ parameter vector with the intercept α in the first position. The $N \times 1$ vector of random disturbances $\mathbf{e}$ has $E(\mathbf{e}) = \mathbf{0}$ and diagonal **covariance** matrix

$$\boldsymbol{\Sigma} = \text{cov}(\mathbf{e}, \mathbf{e}') = \begin{bmatrix} \sigma_1^2 & \dots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \dots & \sigma_N^2 \end{bmatrix} \quad (4)$$

The weighted least-squares estimator of $\boldsymbol{\beta}$ is

$$\hat{\boldsymbol{\beta}}_w = (\mathbf{X}'\boldsymbol{\Sigma}^{-1}\mathbf{X})^{-1}\mathbf{X}'\boldsymbol{\Sigma}^{-1}\mathbf{Y} \quad (5)$$

where $\boldsymbol{\Sigma}^{-1}$ is the $N \times N$ diagonal matrix, the diagonal elements of which are the reciprocals $1/\sigma_i^2$ of the corresponding elements in $\boldsymbol{\Sigma}$. Unfortunately, since the variances of the disturbance terms are rarely known, these results are mainly only of theoretical interest.

Two-Sample t Test

The hypothesis that two independent **normal distribution** means are equal arises frequently in practical data analysis. The Student–Fisher t test of that hypothesis requires that the two populations have a common unknown variance (*see Parametric Tests*). That assumption is easily tested by the ratio $F = s_1^2/s_2^2$ of the independent sample variances (the F test; *see Parametric Tests*). The standard procedure of the t test assumes that $\sigma_1^2 = \sigma_2^2$. Hsu [1] calculated the true type I error probabilities for selected ratios of the population variances $\theta = \sigma_1^2/\sigma_2^2$ and sample sizes $R = N_1/N_2$ for a 0.05 level test (*see Power and Significance Level*). If θ is less than 1 and R is larger than 1, the true type I error rate will be larger than the nominal 0.05 value. If θ and R are both larger than 1, the true type I probability will be less than 0.05. These and other properties of the t test in the presence of unequal variances have been described by Scheffé [2].

The test of the equality of two means of independent normal populations is called the *Behrens–Fisher problem*, after its original investigators. Welch [3, 4] has proposed an alternative test with an approximate t distribution when the population variances are unequal.

The Analysis of Variance

Box [5, 6] has investigated the effect of heteroscedastic disturbance terms on the one- and two-way *analysis of variance* (see **Analysis of Variance**) type I error rates. As in the two-sample *t* test, the effect of unequal variances in the one-way layout is exacerbated by unequal sample sizes. When the sample sizes are equal, the true type I error rates are only slightly higher than the nominal 0.05 value. If the treatments with the smaller variances have larger sample sizes, the type I error rate may be much greater than 0.05. If the opposite condition holds, or if the ratios of the variances roughly follow those of the sample sizes, the true type I error rate may be smaller than the nominal 0.05. For the two-way layout with a single observation in each cell, Box showed that unequal column variances led to row test type I error rates slightly below the nominal 0.05 value, and to column test type I error rates slightly above 0.05. Further remarks on heteroscedasticity in the analysis of variance have been given by Scheffé [2].

Laws of Large Numbers

Introduction

Laws of large numbers concern the behavior of the average of n random variables, $S_n = 1/n \sum_{i=1}^n X_i$, as n grows large. This topic has an interesting early history dating back to the work of Bernoulli and Poisson in the eighteenth and nineteenth centuries; see [1] and [2] for details. For a fairly straightforward modern introduction, see [3]. There are two types of laws, namely, *weak* and *strong*, depending on the mode of convergence of the average S_n to its limit: *weak* refers to convergence in probability and *strong* denotes convergence with probability 1. The difference between these modes is perhaps best appreciated by those with a solid grounding in measure theory; see [4] or [5], for example. There are several versions of the law depending on assumptions regarding (a) the independence of the X_i and (b) whether the X_i follow the same probability distribution. Here, we consider the simplest case in which the X_i are assumed to be mutually independent and follow the same probability distribution with a finite mean μ [5, 6]. More general versions exist in which either, or both, of the assumptions (a) and (b) are relaxed, but then, other conditions are imposed. For example, if the random variables have different means and different variances, but certain moment conditions hold, then the Kolmogorov's strong law is obtained [5]; if the random variables form a stationary stochastic process, then a strong law is available (the "ergodic" theorem [7]); if both assumptions (a) and (b) are weakened while the random variables have a martingale structure, and a moment condition is satisfied, then a strong law is available [5, 8].

The weak law states that S_n converges in probability to μ as $n \rightarrow \infty$; put more precisely, this law states that for any small positive number ϵ , $\Pr\{|S_n - \mu| < \epsilon\} \rightarrow 1$ as $n \rightarrow \infty$. The strong law states that S_n converges to μ with probability 1 as $n \rightarrow \infty$; put more precisely, this law states that for any small positive number ϵ , $\lim_{n \rightarrow \infty} \Pr\{|S_n - \mu| < \epsilon\} = 1$. We now consider three applications of the law.

Application 1 The frequentist concept of probability is based on the notion of the stabilization

of relative frequency. Suppose that n independent experiments are conducted under identical conditions, and suppose that, in each experiment, the event A either occurs, with probability π , or does not occur, with probability $1 - \pi$. In the i th experiment, let X_i take the value 1 if A occurs, and 0 if A does not occur ($i = 1, \dots, n$). Then S_n , the proportion of times that the event A occurs, is the relative frequency of the event A in the first n experiments and by the strong law, as $n \rightarrow \infty$, S_n converges with probability 1 to π , the true probability of the event A .

Application 2 Suppose that it is of interest to estimate the mean and variance of a quality characteristic of a production process, and that measurements are available from a random sample of n products from the process. Let X_i be a random variable representing the quality characteristic for the i th product and suppose that the X_i have a finite mean μ and variance σ^2 ($i = 1, \dots, n$). Consider the usual unbiased estimators S_n of μ and $T_n = n/(n-1)\{1/n \sum_{i=1}^n X_i^2 - \bar{X}^2\}$ of σ^2 . Then, from the strong law, it follows that S_n converges with probability 1 to the population mean μ , that $1/n \sum_{i=1}^n X_i^2$ converges with probability 1 to the expectation of the X_i^2 (which is $\mu^2 + \sigma^2$), and, therefore, that T_n converges with probability 1 to the population variance σ^2 . These results provide theoretical support for the strong consistency of statistical estimation for the sample estimators S_n and T_n (see **Estimation**).

JIM W. KAY

Least-Squares Estimation

Introduction

We present an explicit expression for the least-squares estimator $\hat{\beta}$ of β in the linear regression model, and also give its **covariance** matrix. The calculations are illustrated with a numerical example. The F statistic for testing linear hypotheses on β is also given. We conclude with some extensions.

The method of least-squares estimates parameters by minimizing the squared discrepancies between observed data, on the one hand, and their expected values on the other. We will study the method in the context of a regression problem, where the variation in one variable, called the *response variable*, Y , can be partly explained by the variation in the other variables, called *covariables*, X . For example, variation in exam results, Y , are mainly caused by variation in abilities and diligence, X , of the students, or variation in survival times, Y , are primarily due to variations in environmental conditions X . Given the value of X , the best prediction of Y (in terms of mean square error – see **Estimation**) is the mean $f(X)$ of Y given X . We say that Y is a function of X plus noise:

$$Y = f(X) + \text{noise} \quad (1)$$

The function f is called a *regression function*. It is to be estimated from n sampled covariables and their responses $(x_1, y_1), \dots, (x_n, y_n)$.

Suppose f is known up to a finite number $p \leq n$ of parameters $\beta = (\beta_1, \dots, \beta_p)'$, that is, $f = f_\beta$. We estimate β by the value $\hat{\beta}$ that gives the best fit to the data. The least-squares estimator, denoted by $\hat{\beta}$, is that value of b that minimizes

$$\sum_{i=1}^n (y_i - f_b(x_i))^2 \quad (2)$$

over all possible values of b .

The least-squares criterion is a computationally convenient measure of fit. It corresponds to *maximum-likelihood estimation* when the noise is normally distributed with equal variances. Other measures of fit are sometimes used, for example least-absolute deviations, which is more robust against **outliers**.

Linear Regression

Consider the case where f_β is a linear function of β , that is,

$$f_\beta(\mathbf{X}) = X_1\beta_1 + \dots + X_p\beta_p \quad (3)$$

Here $(X_1, \dots, X_p)$ stand for the observed variables used in $f_\beta(X)$.

To write down the least-squares estimator for the linear regression model, it will be convenient to use matrix notation. Let $\mathbf{y} = (y_1, \dots, y_n)'$ and let $\mathbf{X}$ be the $n \times p$ data matrix of the n observations on the p variables

$$\mathbf{X} = \begin{pmatrix} \mathbf{x}_{1,1} & \dots & \mathbf{x}_{1,p} \\ \vdots & \dots & \vdots \\ \mathbf{x}_{n,1} & \dots & \mathbf{x}_{n,p} \end{pmatrix} = (\mathbf{x}_1 \dots \mathbf{x}_p) \quad (4)$$

where $\mathbf{x}_j$ is the column vector containing the n observations on variable j , $j = 1, \dots, p$. Denote the squared length of an n -dimensional vector $\mathbf{v}$ by $\|\mathbf{v}\|^2 = \mathbf{v}'\mathbf{v} = \sum_{i=1}^n v_i^2$. Then equation (2) can be written as

$$\|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 \quad (5)$$

which is the squared distance between the vector $\mathbf{y}$ and the linear combination $\mathbf{b}$ of the columns of the matrix $\mathbf{X}$. The distance is minimized by taking the *projection* of $\mathbf{y}$ on the space spanned by the columns of $\mathbf{X}$ (see Figure 1).

Suppose now that $\mathbf{X}$ has full-column rank, that is, no column in $\mathbf{X}$ can be written as a linear

Figure 1 The projection of the vector $\mathbf{y}$ on the plane spanned by $\mathbf{x}$

2 Least-Squares Estimation

combination of the other columns. Then, the least-squares estimator $\hat{\beta}$ is given by

$$\hat{\beta} = (\mathbf{X}'\mathbf{X})^{-1} \mathbf{X}'\mathbf{y} \quad (6)$$

The Variance of the Least-Squares Estimator

To construct **confidence intervals** for the components of $\hat{\beta}$, or linear combinations of these components, one needs an estimator of the covariance matrix of $\hat{\beta}$. Now, it can be shown that, given $\mathbf{X}$, the covariance matrix of the estimator $\hat{\beta}$ is equal to

$$(\mathbf{X}'\mathbf{X})^{-1} \sigma^2 \quad (7)$$

where σ^2 is the variance of the noise. As an estimator of σ^2 , we take

$$\hat{\sigma}^2 = \frac{1}{n-p} \|\mathbf{y} - \mathbf{X}\hat{\beta}\|^2 = \frac{1}{n-p} \sum_{i=1}^n \hat{e}_i^2 \quad (8)$$

where the $\hat{e}_i$ are the **residuals**

$$\hat{e}_i = y_i - \mathbf{x}_{i,1}\hat{\beta}_1 - \cdots - \mathbf{x}_{i,p}\hat{\beta}_p \quad (9)$$

The covariance matrix of $\hat{\beta}$ can, therefore, be estimated by

$$(\mathbf{X}'\mathbf{X})^{-1} \hat{\sigma}^2 \quad (10)$$

For example, the estimate of the variance of $\hat{\beta}_j$ is

$$\text{var}(\hat{\beta}_j) = \tau_j^2 \hat{\sigma}^2 \quad (11)$$

where τ_j^2 is the j th element on the diagonal of $(\mathbf{X}'\mathbf{X})^{-1}$. A confidence interval for β_j is now obtained by taking the least-squares estimator $\hat{\beta}_j \pm$ a margin:

$$\hat{\beta}_j \pm c \sqrt{\text{var}(\hat{\beta}_j)} \quad (12)$$

where c depends on the chosen confidence level. For a 95% confidence interval, the value $c = 1.96$ is a good approximation when n is large. For smaller values of n , one usually takes a more conservative c using the tables for the student distribution with $n - p$ degrees of freedom.

Numerical Example

Consider a regression with constant, linear, and quadratic terms:

$$f_{\beta}(X) = \beta_1 + X\beta_2 + X^2\beta_3 \quad (13)$$

We take $n = 100$ and $x_i = i/n$, $i = 1, \dots, n$. The matrix $\mathbf{X}$ is now

$$\mathbf{X} = \begin{pmatrix} 1 & x_1 & x_1^2 \\ \vdots & \vdots & \vdots \\ 1 & x_n & x_n^2 \end{pmatrix} \quad (14)$$

This gives

$$\mathbf{X}'\mathbf{X} = \begin{pmatrix} 100 & 50.5 & 33.8350 \\ 50.5 & 33.8350 & 25.5025 \\ 33.8350 & 25.5025 & 20.5033 \end{pmatrix} \quad (15)$$

$$(\mathbf{X}'\mathbf{X})^{-1} = \begin{pmatrix} 0.0937 & -0.3729 & 0.3092 \\ -0.3729 & 1.9571 & -1.8189 \\ 0.3092 & -1.8189 & 1.8009 \end{pmatrix} \quad (16)$$

We simulated n independent standard normal random variables $e_1, \dots, e_n$, and calculated for $i = 1, \dots, n$,

$$y_i = 1 - 3x_i + e_i \quad (17)$$

Thus, in this example, the parameters are

$$\begin{pmatrix} \beta_1 \\ \beta_2 \\ \beta_3 \end{pmatrix} = \begin{pmatrix} 1 \\ -3 \\ 0 \end{pmatrix} \quad (18)$$

Moreover, $\sigma^2 = 1$. Because this is a simulation, these values are known.

To calculate the least-squares estimator, we need the values of $\mathbf{X}'\mathbf{y}$, which, in this case, turn out to be

$$\mathbf{X}'\mathbf{y} = \begin{pmatrix} -64.2007 \\ -52.6743 \\ -42.2025 \end{pmatrix} \quad (19)$$

The least-squares estimate is thus

$$\hat{\beta} = \begin{pmatrix} 0.5778 \\ -2.3856 \\ -0.0446 \end{pmatrix} \quad (20)$$

From the data, we also calculated the estimated variance of the noise, and found the value

$$\hat{\sigma}^2 = 0.883 \quad (21)$$

The data are represented in Figure 2. The dashed line is the true regression $f_{\beta}(x)$. The solid line is the estimated regression $f_{\hat{\beta}}(x)$.

The estimated regression is barely distinguishable from a straight line. Indeed, the value $\hat{\beta}_3 = -0.0446$

Figure 2 Observed data, true regression (dashed line), and least-squares estimate (solid line)

of the quadratic term is small. The estimated variance of $\hat{\beta}_3$ is

$$\text{var}(\hat{\beta}_3) = 1.8009 \times 0.883 = 1.5902 \quad (22)$$

Using $c = 1.96$ in equation (12), we find the confidence interval

$$\beta_3 \in -0.0446 \pm 1.96\sqrt{1.5902} = [-2.5162, 2.470] \quad (23)$$

Thus, β_3 is not significantly different from zero at the 5% level, and, hence, we do not reject the hypothesis $H_0 : \beta_3 = 0$.

Below, we will consider general test statistics for testing hypotheses on β . In this particular case, the test statistic takes the form

$$T^2 = \frac{\hat{\beta}_3^2}{\text{var}(\hat{\beta}_3)} = 0.0012 \quad (24)$$

Using this test statistic is equivalent to the above method based on the confidence interval. Indeed, as $T^2 < (1.96)^2$, we do not reject the hypothesis $H_0 : \beta_3 = 0$.

Under the hypothesis $H_0 : \beta_3 = 0$, we use the least-squares estimator

$$\begin{pmatrix} \hat{\beta}_{1,0} \\ \hat{\beta}_{2,0} \end{pmatrix} = (\mathbf{X}_0' \mathbf{X}_0)^{-1} \mathbf{X}_0' \mathbf{y} = \begin{pmatrix} 0.5854 \\ -2.4306 \end{pmatrix} \quad (25)$$

Here,

$$\mathbf{X}_0 = \begin{pmatrix} 1 & x_1 \\ \vdots & \vdots \\ 1 & x_n \end{pmatrix} \quad (26)$$

It is important to note that setting β_3 to zero changes the values of the least-squares estimates of β_1 and β_2 :

$$\begin{pmatrix} \hat{\beta}_{1,0} \\ \hat{\beta}_{2,0} \end{pmatrix} \neq \begin{pmatrix} \hat{\beta}_1 \\ \hat{\beta}_2 \end{pmatrix} \quad (27)$$

This is because $\hat{\beta}_3$ is correlated with $\hat{\beta}_1$ and $\hat{\beta}_2$. One may verify that the **correlation** matrix of $\hat{\beta}$ is

$$\begin{pmatrix} 1 & -0.8708 & 0.7529 \\ -0.8708 & 1 & -0.9689 \\ 0.7529 & -0.9689 & 1 \end{pmatrix} \quad (28)$$

Testing Linear Hypotheses

The testing problem considered in the numerical example is a special case of testing a linear hypothesis $H_0 : A\beta = 0$, where A is some $r \times p$ matrix. As another example of such a hypothesis, suppose we want to test whether two coefficients are equal, say $H_0 : \beta_1 = \beta_2$. This means there is one restriction $r = 1$, and we can take A as the $1 \times p$ row vector

$$A = (1, -1, 0, \dots, 0) \quad (29)$$

In general, we assume that there are no linear dependencies in the r restrictions $A\beta = 0$. To test the linear hypothesis, we use the statistic

$$T^2 = \frac{\|\mathbf{X}\hat{\beta}_0 - \mathbf{X}\hat{\beta}\|^2/r}{\hat{\sigma}^2} \quad (30)$$

where $\hat{\beta}_0$ is the least-squares estimator under $H_0 : A\beta = 0$. In the numerical example, this statistic takes the form given in equation (24). When the noise is normally distributed, critical values can be found in a table for the F distribution with r and $n - p$ **degrees of freedom**. For large n , approximate critical values are in the table of the χ^2 distribution with r degrees of freedom.

Some Extensions

Weighted Least-Squares

In many cases, the variance σ_i^2 of the noise at measurement i depends on x_i . Observations in which

4 Least-Squares Estimation

σ_i^2 is large are less accurate, and, hence, should play a smaller role in the estimation of β . The *weighted* least-squares estimator is the value of b that minimizes the criterion

$$\sum_{i=1}^n \frac{(y_i - f_b(x_i))^2}{\sigma_i^2} \quad (31)$$

over all possible b . In the linear case, this criterion is numerically of the same form, as we can make the change of variables $\tilde{y}_i = y_i/\sigma_i$ and $\tilde{\mathbf{x}}_{i,j} = \mathbf{x}_{i,j}/\sigma_i$.

Nonlinear Regression

When f_β is a nonlinear function of β , one usually needs iterative algorithms to find the least-squares estimator. The variance can then be approximated

as in the linear case, with $\dot{f}_\beta(x_i)$ taking the role of the rows of $\mathbf{X}$. Here, $\dot{f}_\beta(x_i) = \partial f_\beta(x_i)/\partial \beta$ is the row vector of derivatives of $f_\beta(x_i)$. For more details, see e.g. [1].

Moments

Introduction

Moments are an important class of *expectations* used to describe probability distributions. Together, the entire set of moments of a random variable will generally determine its probability distribution exactly.

There are three main types of moments:

1. raw moments,
2. central moments, and
3. factorial moments.

Raw Moments

Where a random variable is denoted by the letter X , and k is any positive integer, the k th raw moment of X is defined as $E(X^k)$, the expectation of the random variable X raised to the power k . Raw moments are usually denoted by μ'_k where $\mu'_k = E(X^k)$, if that expectation exists. The first raw moment of X is $\mu'_1 = E(X)$, also referred to as the *mean of X* . The second raw moment of X is $\mu'_2 = E(X^2)$, the third $\mu'_3 = E(X^3)$, and so on. If the k th moment of X exists, then all moments of lower order also exist. Therefore, if the $E(X^2)$ exists, it follows that $E(X)$ exists.

Central Moments

Where X again denotes a random variable and k is any positive integer, the k th central moment of X is defined as $E[(X - c)^k]$, the expectation of X minus a constant, all raised to the power k . Where the constant is the mean of the random variable, this is referred to as the *k th central moment around the mean*. Central moments around the mean are usually denoted by μ_k where $\mu_k = E[(X - \mu_X)^k]$. The first central moment is equal to zero as $\mu_1 = E[(X - \mu_X)] = E(X) - E(\mu_X) = \mu_X - \mu_X = 0$. In fact, if the probability distribution is symmetrical around the mean (e.g., the **normal distribution**) all odd central moments of X around the mean are equal to zero, provided they exist. The most important central moment is the second central moment of X around the mean. This

Figure 1 An example of an asymmetrical probability distribution where the third central moment around the mean is equal to zero

is $\mu_2 = E[(X - \mu_X)^2]$, the *variance* (see **Variance**) of X .

The third central moment about the mean, $\mu_3 = E[(X - \mu_X)^3]$, is sometimes used as a measure of asymmetry or **skewness**. As an odd central moment around the mean, μ_3 is equal to zero if the probability distribution is symmetrical. If the distribution is negatively skewed, the third central moment about the mean is negative, and if it is positively skewed, the third central moment around the mean is positive. Thus, knowledge of the shape of the distribution provides information about the value of μ_3 . Knowledge of μ_3 does not necessarily provide information about the shape of the distribution, however. A value of zero may not indicate that the distribution is symmetrical. As an illustration of this, μ_3 is approximately equal to zero for the distribution depicted in Figure 1, but it is not symmetrical. The third central moment is therefore not used much in practice.

The fourth central moment about the mean, $\mu_4 = E[(X - \mu_X)^4]$, is sometimes used as a measure of excess or **kurtosis**. This is the degree of flatness of the distribution near its center. The coefficient of kurtosis ($\mu_4/\sigma^4 - 3$) is sometimes used to compare an observed distribution to that of a normal curve. Positive values are thought to be indicative of a distribution that is more peaked around its center than that of a normal curve, and negative values are thought to be indicative of a distribution that is more flat around

its center than that of a normal curve. However, as was the case for the third central moment around the mean, the coefficient of kurtosis does not always indicate what it is supposed to.

Factorial Moments

Finally, where X denotes a random variable and k is any positive integer, the k th factorial moment of X is defined as the following expectation $E[X(X-1)\dots(X-k+1)]$. The first factorial moment of X is therefore $E(X)$, the second factorial moment of X is $E[(X-1+1)(X-2+1)] = E(X^2 - X)$, and so on. Factorial moments are easier to calculate than raw moments for some random variables (usually discrete). As raw moments can be obtained from factorial moments and *vice versa*, it is sometimes easier to obtain the raw moments for a random variable from its factorial moments.

Moment Generating Function

For each type of moment, there is a function that can be used to generate all of the moments of a random variable or probability distribution. This is referred to as the *moment generating function* and denoted by mgf, $m_X(t)$ or $m(t)$. In practice, however,

it is often easier to calculate moments directly. The main use of the mgf is therefore in characterizing a distribution and for theoretical purposes. For instance, if a mgf of a random variable exists, then this mgf uniquely determines the corresponding distribution function. As such, it can be shown that if the mgfs of two random variables both exist and are equal for all values of t in an interval around zero, then the two cumulative distribution functions are equal. However, existence of all moments is not equivalent to existence of the mgf.

More information on the topic of moments and mgfs is given in [1-3].

Probability Plots

Introduction

Probability plots are often used to compare two empirical distributions (*see Estimation*), but they are particularly useful to evaluate the shape of an empirical distribution against a theoretical distribution. For example, we can use a probability plot to examine the degree to which an empirical distribution differs from a **normal distribution**.

There are two major forms of probability plots, known as *probability–probability (P–P) plots* and *quantile–quantile (Q–Q) plots*. They both serve essentially the same purpose, but plot different functions of the data.

An Example

It is easiest to see the difference between P–P and Q–Q plots with a simple example. The data displayed in Table 1 are derived from data collected by Compas (personal communication) on the effects of stress on

cancer patients. Each of the 41 patients completed the externalizing behavior scale of the Brief Symptom Inventory. We wish to judge the normality of the sample data. A histogram for these data is presented in Figure 1 with a normal distribution superimposed. The sample mean is 12.10, and the sample standard deviation is 10.32.

P–P Plots

A P–P plot displays the cumulative probability of the obtained data on the x axis and the corresponding expected cumulative probability for the reference distribution (in this case, the normal distribution) on the y axis. For example, a raw score of 15 for our data had a cumulative probability of 0.756. It also had a z score, given the mean and standard deviation of the sample, of 0.28. For a normal distribution, we expect to find 61% of the distribution falling at or below $z = 0.28$. So, for this observation, we had considerably more scores (75.6%) falling at or below 15 than we would have expected if the distribution were normal (61%). From Table 1, you

Table 1 Frequency distribution of externalizing scores with normal probabilities and **quantiles**

Score	Frequency	Percent	Cumulative percent	z	CDF normal	Normal quantile
0	3	7.3	7.3	−1.17	0.12	−3.01

2 Probability Plots

Figure 1 Histogram of externalizing scores with normal curve superimposed

Figure 2 P-P plot of obtained distribution against the normal distribution

can see the results of similar calculations for the full data set. These are displayed in columns 4 and 6.

If we plot the obtained cumulative percentage on the x axis and the expected cumulative percentage on the y axis, we obtain the results shown in Figure 2. Here, a line drawn at 45° is superimposed. If the data had been exactly normally distributed, the points would have fallen on that line. It is clear from the figure that this was not the case. The points deviate noticeably from the line, and thus, from normality.

Q-Q Plots

A Q-Q plot resembles a P-P plot in many ways, but it displays the observed values of the data on the x axis and the corresponding expected values from a normal distribution on the y axis. The expected values are based on the *quantiles* of the distribution. To take our example of a score of 15 again, we know that 75.6% of the observations fell at or below 15, placing 15 at the 75.6 percentile. If we had a normal distribution with a mean of 12.10 and a standard deviation of 10.32, we would

Figure 3 Q–Q plot of obtained distribution against the normal distribution

expect the 75.6 percentile to fall at a score of 19.16. We can make similar calculations for the remaining data, and these are shown in column 7 of Table 1. (The final cumulative percentage has been treated as 99.9 instead of 100 because the normal distribution runs to infinity and the quantile for 100% would be undefined.)

The plot of these values can be seen in Figure 3, where, again, a straight line is superimposed representing the results that we would have if the data were perfectly normally distributed. Again, we can see significant departure from normality.

Quantiles

A quantile of a distribution is the value such that a proportion p of the population values are less than or equal to it. In other words, the p th quantile is the value that cuts off a certain proportion p of the area under the probability distribution function (see **Cumulative Distribution Function (CDF)**). It is sometimes known as a *theoretical quantile* or a *population quantile* and is denoted by $Q_i(p)$. Quantiles for common distributions are easily obtained using routines for the inverse cumulative distribution function (inverse **cdf**) found in many popular statistical packages.

For example, the 0.5 quantile (which we also recognize as the median or 50th percentile) of a standard **normal distribution** is $P(x \leq x_{0.5}) = \Phi^{-1}(0.5) = 0$, where $\Phi^{-1}(\cdot)$ denotes the inverse cdf of that distribution. Equally easily, we locate the 0.5 quantile for an exponential distribution (see **Probability Density Functions**) with mean of 1 as 0.6931. Other useful quantiles such as the lower and upper **quartiles** (0.25 and 0.75 quantiles) can be obtained in a similar way.

However, we are more likely to be concerned with quantiles associated with data. Here, the *empirical quantile* $Q(p)$ is that point on the data scale that splits the data (the empirical distribution; see **Estimation**) into two parts so that a proportion p of the observations fall below it and the rest lie above. Although each data point is itself some quantile, obtaining a *specific* quantile requires a more pragmatic approach.

Consider the following 10 observations, ordered from the smallest to the largest.

274, 302, 334, 430, 489, 703, 978, 1656, 1697, 2745

Imagine that we are interested in the 0.5 and 0.85 quantiles for these data. With 10 data points, the point $Q(0.5)$ on the data scale that has half of the observations below it and half above does not actually correspond to a member of the sample but lies *somewhere* between the middle two values 489 and 703. Also, we have no way of splitting off exactly 0.85 of the data. So, where do we go from here?

Several different remedies have been proposed, each of which essentially entails a modest redefinition of quantile. For most practical purposes, any differences between the estimates obtained from the

various versions will be negligible. The only method that we shall consider here is the one that is also used by Minitab and SPSS (but see [1] for a description of an alternative favored by the *exploratory data analysis* (EDA) community).

Suppose that we have n ordered observations x_i ($i = 1-n$). These split the data scale into $n + 1$ segments: one below the smallest observation, $n - 1$ between each adjacent pair of values and one above the largest. The proportion p of the distribution that lies below the i th observation is then estimated by $i/(n + 1)$. Setting this equal to p gives $i = p(n + 1)$. If i is an integer, the i th observation is taken to be $Q(p)$. Otherwise, we take the integer part of i , say j , and look for $Q(p)$ between the j th and $j + 1$ th observations. Assuming simple linear interpolation, $Q(p)$ lies a fraction $(i - j)$ of the way from x_j to x_{j+1} and is estimated by

$$Q(p) = x_j + (x_{j+1} - x_j) \times (i - j) \quad (1)$$

A point to note is that we cannot determine quantiles in the tails of the distribution for $p < 1/(n + 1)$ or $p > n/(n + 1)$ since these take us outside the range of the data. If extrapolation is unavoidable, it is safest to define $Q(p)$ for all P values in these two regions as x_1 and x_n , respectively.

Returning to the 10 data points given before, we note that for the 0.5 quantile, $i = 0.5 \times 11 = 5.5$, which is not an integer so $Q(0.5) = 489 + (703 - 489) \times (5.5 - 5) = 596$, which is exactly half way between the fifth and sixth observations. For the 0.85 quantile, $i = 0.85 \times 11 = 9.35$, so the required value will lie 0.35 of the way between the 9th and 10th observations, and is estimated by $Q(0.85) = 1697 + (2745 - 1697) \times (9.35 - 9) = 2063.8$.

From a plot of the empirical quantiles $Q(p)$, that is, the data, against proportion p as in Figure 1, we can get some feeling for the distributional properties of our sample (see also **Probability Plots**). For example, we can read off rough values of important quantiles such as the median and quartiles. Moreover, the increasing steepness of the slope on the right-hand side indicates a lower density of data points in that region and thereby alerts us to **skewness** and possible **outliers**. Note that we have also defined $Q(p) = x_1$ when $p < 1/11$ and $Q(p) = x_{10}$ when $p > 10/11$. Clearly, extrapolation would not be advisable, especially at the upper end.

Figure 1 Quantile plot for Necker cube reversal times

It is possible to obtain *confidence intervals* for quantiles, and information on how these are constructed can be found, for example in [2]. Routines for these procedures are available within certain statistical packages such as SAS and S-PLUS.

Quantiles play a central role within *exploratory data analysis*. The median ($Q(0.5)$), upper and lower quartiles ($Q(0.75)$ and $Q(0.25)$), and the maximum and minimum values, which constitute the so-called five-number summary, are the basic elements of a box plot. An empirical quantile–quantile plot (see **Probability Plots**) is a scatterplot of the paired empirical quantiles of two samples of data, while the symmetry plot is a scatterplot of the paired empirical quantiles from a single sample, which has

been split and folded at the median. Of course, for these latter plots there is no need for the P values to be explicitly identified.

Finally, it is worth noting that the term *quantile* is a general one referring to the class of statistics, which split a distribution according to a proportion p that can be *any* value between 0 and 1. As we have seen, well-known measures that have specific P values, such as the median, quartile, and percentile (on Galton's original idea of splitting by 100ths [3]), belong to this group. Nowadays, however, quantile and percentile are used almost interchangeably: the only difference is whether p is expressed as a decimal fraction or as a percentage.

Time Series Analysis

Time Series Data

A time series is a set of observations x_t , each one associated with a particular time t , and usually displayed in a *time series plot* of x_t as a function of t . The set of times T at which observations are recorded may be a discrete set, as is the case when the observations are recorded at uniformly spaced times (e.g., daily rainfall, hourly temperature, annual income, etc.), or it may be a continuous interval, as when the data is recorded continuously (e.g., by a seismograph or electrocardiograph). A very large number of practical problems involve observations that are made at uniformly spaced times. For this reason, this article focuses on this case, indicating briefly how missing values and irregularly spaced data can be handled.

Example 1 Figure 1 shows the number of accidental deaths recorded monthly in the United States for the years 1973–1978. The graph strongly suggests (as is usually the case for monthly data) the presence of a periodic component with period 12 corresponding to the seasonal cycle of 12 months, as well as a smooth trend accounting for the relatively slow change in level of the series, and a random component accounting for irregular deviations from a deterministic model involving trend and seasonal components only.

Example 2 Figure 2 shows the closing value in Australian dollars of the Australian All-Ordinaries index (an average of 100 stocks sold on the Australian Stock Exchange) on 521 successive trading days, ending on July 18, 1994. It displays irregular variation around a rather strong trend. Figure 3 shows the daily percentage changes in closing value of the index for each of the 520 days ending on July 18, 1994. The trend apparent in Figure 2 has virtually disappeared, and the series appears to be varying randomly around a mean value close to zero.

Objectives

The objectives of time series analysis are many and varied, depending on the particular field of application. From the observations $x_1, \dots, x_n$, we

may wish to make inferences about the way in which the data are generated, to predict future values of

2 Time Series Analysis

the series (forecasting), to detect a “signal” hidden in noisy data, or simply to find a compact description of the available observations. In industrial statistics, time series analysis plays an important role in process monitoring and adjustment (see [1]).

In order to achieve these goals, it is necessary to postulate a mathematical model (or family of models), according to which we suppose that the data are generated. Once an appropriate family has been selected, we then select a *specific* model by estimating model parameters and checking the resulting model for goodness of fit to the data. Once we are satisfied that the selected model provides a good representation of the data, we use it to address questions of interest. It is rarely the case that there is a “true” mathematical model underlying empirical data, however, systematic procedures have been developed for selecting the best model, according to clearly specified criteria, within a broad class of candidates.

Time Series Models

As indicated above, the graph of the accidental deaths series in Figure 1 suggests representing x_t as the sum of a slowly varying *trend* component, a period-12 *seasonal* component, and a *random* component that accounts for the irregular deviations from the sum of the other two components. In order to take account of the randomness, we suppose that for each t , the observation x_t is just one of many possible values of a random variable X_t that we *might* have observed. This leads to the following *classical decomposition model* for the accidental deaths data,

$$X_t = m_t + s_t + Y_t, \quad t = 1, 2, 3, \dots \quad (1)$$

where the sequence $\{m_t\}$ is the *trend* component describing the long-term movement in the level of the series, $\{s_t\}$ is a *seasonal* component with known period (in this case, 12), and $\{Y_t\}$ is a sequence of random variables with mean zero, referred to as the *random component*. If we can characterize m_t , s_t , and Y_t in simple terms and in such a way that the model (1) provides a good representation of the data, then we can proceed to use the model to make forecasts or to address other questions related to the series. Completing the specification of the model by estimating the trend and seasonal components and characterizing the random component is a major part of time series

analysis. The model (1) is sometimes referred to as an *additive decomposition model*. Provided the observations are all positive, the *multiplicative model*,

$$X_t = m_t s_t Y_t \quad (2)$$

can be reduced to an additive model by taking logarithms of each side to get an additive model for the logarithms of the data.

The general form of the additive model (1) supposes that the seasonal component s_t has known period d (12 for monthly data, 4 for quarterly data, etc.), and satisfies the conditions

$$s_{t+d} = s_t \text{ and } \sum_{t=1}^d s_t = 0 \quad (3)$$

while $\{Y_t\}$ is a *weakly stationary sequence of random variables*, that is, a sequence of random variables satisfying the conditions,

$$E(Y_t) = \mu, \quad E(Y_t^2) < \infty \quad (4)$$

and

$$\text{Cov}(Y_{t+h}, Y_t) = \gamma(h) \text{ for all } t \quad (5)$$

with $\mu = 0$. The function γ is called the *autocovariance function* of the sequence $\{Y_t\}$, and the value $\gamma(h)$ is the *autocovariance at lag h* . In the special case when the random variables Y_t are independent and identically distributed, the model (1) is a classical regression model and $\gamma(h) = 0$ for all $h \neq 0$. However, in time series analysis, it is the dependence between Y_{t+h} and Y_t that is of special interest, and it allows the possibility of using past observations to obtain forecasts of future values that are better in some average sense than just using the expected value of the series. A measure of this dependence is provided by the autocovariance function. A more convenient measure (since it is independent of the origin and scale of measurement of Y_t) is the *autocorrelation function* (see **Autocorrelation Function**),

$$\rho(h) = \frac{\gamma(h)}{\gamma(0)} \quad (6)$$

From observed values $y_1, \dots, y_n$ of a weakly stationary sequence of random variables $\{Y_t\}$, good estimators of the mean $\mu = E(Y_t)$ and the autocovariance function $\gamma(h)$ are the *sample mean* and *sample autocovariance function*,

$$\hat{\mu} = \frac{1}{n} \sum_{i=1}^n y_i \quad (7)$$

and

$$\hat{\gamma}(h) = \frac{1}{n} \sum_{i=1}^{n-|h|} (y_{i+|h|} - \hat{\mu})(y_i - \hat{\mu}), \quad -n < h < n \quad (8)$$

respectively. The autocorrelation function of $\{Y_t\}$ is estimated by the *sample autocorrelation function*,

$$\hat{\rho}(h) = \frac{\hat{\gamma}(h)}{\hat{\gamma}(0)} \quad (9)$$

Elementary techniques for estimating m_t and s_t can be found in many texts on time series analysis (e.g. [2]). Once estimators $\hat{m}_t$ of m_t and $\hat{s}_t$ of s_t have been obtained, they can be subtracted from the observations to yield the **residuals**,

$$y_t = x_t - \hat{m}_t - \hat{s}_t \quad (10)$$

A stationary time series model can then be fitted to the residual series to complete the specification of the model. The model is usually chosen from the class of *autoregressive moving average* (or **ARMA**) *processes*, defined below in the section titled “ARMA processes”.

Instead of estimating and subtracting the trend and seasonal components to generate a sequence of residuals, an alternative approach, developed by Box *et al.* [3], is to apply *difference operators* to the original series to remove trend and seasonality. The *backward shift operator* B is an operator that, when applied to X_t , gives X_{t-1} . Thus,

$$BX_t = X_{t-1}, \quad B^j X_t = X_{t-j}, \quad j = 2, 3, \dots \quad (11)$$

The *lag-1 difference operator* is the operator $\nabla = (1 - B)$. Thus,

$$\nabla X_t = (1 - B)X_t = X_t - X_{t-1} \quad (12)$$

When applied to a polynomial trend of degree p , the operator ∇ reduces it to a polynomial of degree $p - 1$. The operator ∇^p , denoting p successive applications of ∇ , therefore, reduces any polynomial trend of degree p to a constant. Usually, a small number of applications of ∇ is sufficient to eliminate trends encountered in practice. Application of the *lag- d difference operator*, $\nabla_d = (1 - B^d)$ (not to be confused with ∇^d) to X_t gives

$$\nabla_d X_t = (1 - B^d)X_t = X_t - X_{t-d} \quad (13)$$

eliminating any seasonal component with period d . In the Box–Jenkins approach to time series modeling, the operators ∇ and ∇_d are applied as many times as is necessary to eliminate trend and seasonality, and the sample mean of the differenced data is subtracted to generate a sequence of residuals y_t , which are then modeled with a suitably chosen ARMA process in the same way as the residuals (equation (10)).

Figure 4 shows the effect of applying the operator ∇_{12} to the accidental deaths series of Figure 1. The seasonal component is no longer apparent, but there is still an approximately linear trend. Further application of the operator ∇ yields the series shown in Figure 5 with relatively constant level. This new series is a good candidate for representation by a stationary time series model.

Figure 4 The differenced series $\{\nabla_{12}x_t, t = 13, \dots, 72\}$ derived from the monthly accidental deaths $\{x_1, \dots, x_{72}\}$ shown in Figure 1

Figure 5 The differenced series $\{\nabla\nabla_{12}x_t, t = 14, \dots, 72\}$ derived from the monthly accidental deaths $\{x_1, \dots, x_{72}\}$ shown in Figure 1

The daily percentage returns on the Australian All-Ordinaries index shown in Figure 2 already show no sign of trend or seasonality, and can be modeled as a stationary sequence without preliminary detrending or deseasonalizing.

In cases where the variability of the observed data appears to change with the level of the data, a preliminary transformation, prior to detrending and deseasonalizing, may be required to stabilize the variability. For this purpose, a member of the family of *Box–Cox transformations* (see **Box and Cox Transformation**; [2]) is frequently used.

ARMA Processes

For modeling the residuals $\{y_t\}$ (found as described above), a very useful parametric family of zero-mean stationary sequences is furnished by the *ARMA processes*. The $\text{ARMA}(p, q)$ process $\{Y_t\}$ with autoregressive coefficients, $\phi_1, \dots, \phi_p$, moving average coefficients, $\theta_1, \dots, \theta_q$, and white noise variance σ^2 , is defined as a weakly stationary solution of the difference equations,

$$(1 - \phi_1 B - \dots - \phi_p B^p)Y_t = (1 + \theta_1 + \dots + \theta_q B^q)Z_t, \quad t = 0, \pm 1, \pm 2, \dots \quad (14)$$

where B is the backward shift operator, the polynomials $\phi(z) = 1 - \phi_1 z - \dots - \phi_p z^p$ and $\theta(z) = 1 + \theta_1 z + \dots + \theta_q z^q$ have no common factors, and $\{Z_t\}$ is a sequence of uncorrelated random variables with mean zero and variance σ^2 . Such a sequence $\{Z_t\}$ is said to be *white noise with mean zero and variance σ^2* , indicated more concisely by writing $\{Z_t\} \sim \text{WN}(0, \sigma^2)$.

Equation (14) has a unique stationary solution if, and only if, the equation $\phi(z) = 0$ has no root with $|z| = 1$, however, the possible values of $\phi_1, \dots, \phi_p$ are usually assumed to satisfy the stronger restriction,

$$\phi(z) \neq 0 \text{ for all complex } z \text{ such that } |z| \leq 1 \quad (15)$$

The unique weakly stationary solution of equation (14) is then

$$Y_t = \sum_{j=0}^{\infty} \psi_j Z_{t-j} \quad (16)$$

where ψ_j is the coefficient of z^j in the power-series expansion,

$$\frac{\theta(z)}{\phi(z)} = \sum_{j=0}^{\infty} \psi_j z^j, \quad |z| \leq 1 \quad (17)$$

Since Y_t in equation (16) is a function only of Z_s , $s \leq t$, the series $\{Y_t\}$ is said to be a *causal function* of $\{Z_t\}$, and the condition (15) is called the *causality condition* for the process (14). (Condition (15) is also frequently referred to as a *stability condition*.)

In the causal case, simple recursions are available for the numerical calculation of the sequence $\{\psi_j\}$ from the autoregressive and moving average coefficients $\phi_1, \dots, \phi_p$, and $\theta_1, \dots, \theta_q$ (see e.g. [2]). For every noncausal ARMA process, there is a causal ARMA process with the same autocovariance function, and, *under the assumption that all the joint distributions of the process are multivariate normal*, with the same joint distributions. This is one reason for restricting attention to causal models. Another practical reason is that if $\{Y_t\}$ is to be simulated sequentially from the sequence $\{Z_t\}$, the causal representation (16) of Y_t does not involve *future* values Z_{t+h} , $h > 0$.

A key feature of ARMA processes for modeling dependence in a sequence of observations is the extraordinarily large range of autocorrelation functions exhibited by ARMA processes of different orders (p, q) as the coefficients $\phi_1, \dots, \phi_p$, and $\theta_1, \dots, \theta_q$, are varied. For example, if we take any set of observations, $x_1, \dots, x_n$ and compute the sample autocorrelations, $\hat{\rho}(0)(=1), \hat{\rho}(1), \dots, \hat{\rho}(n-1)$, then for any $k < n$, it is always possible to find a causal $\text{AR}(k)$ process with autocorrelations $\rho(j)$ satisfying $\rho(j) = \hat{\rho}(j)$ for every $j \leq k$.

The mean of the ARMA process defined by equation (14) is $E(Y_t) = 0$, and the autocovariance function can be found from the equations obtained by multiplying each side of equation (14) by Y_{t-j} , $j = 0, 1, 2, \dots$, taking expectations and solving for $\gamma(j) = E(Y_t Y_{t-j})$. Details can be found in [2].

Example 3 The causal $\text{ARMA}(1, 0)$ or $\text{AR}(1)$ process is a stationary solution of the equations

$$Y_t = \phi Y_{t-1} + Z_t, \quad |\phi| < 1, \quad \{Z_t\} \sim \text{WN}(0, \sigma^2) \quad (18)$$

The autocovariance function of $\{Y_t\}$ is $\rho(h) = \sigma^2 \phi^{|h|} / (1 - \phi^2)$.

Example 4 The ARMA(0, q) or MA(q) process is the stationary series defined by

$$Y_t = \sum_{j=0}^q \theta_j Z_{t-j},$$

$$\theta_0 = 1, \{Z_t\} \sim WN(0, \sigma^2) \quad (19)$$

The autocovariance function of $\{Y_t\}$ is $\gamma(h) = \sigma^2 \sum_{j=0}^{|h|} \theta_j \theta_{j+|h|}$ if $h \leq q$ and $\gamma(h) = 0$ otherwise.

A process $\{X_t\}$ is said to be an *ARMA process with mean μ* if $\{Y_t = X_t - \mu\}$ is an ARMA process as defined by equations of the form (14).

In the following section, we consider the problem of fitting an ARMA model of the form (14), that is, $\phi(B)Y_t = \theta(B)Z_t$, to the residual series $y_1, y_2, \dots$, generated as described in the section titled “Time Series Models”. If the residuals were obtained by applying the differencing operator $(1 - B)^d$ to the original observations $x_1, x_2, \dots$, then we are effectively fitting the model

$$\phi(B)(1 - B)^d X_t = \theta(B)Z_t,$$

$$\{Z_t\} \sim WN(0, \sigma^2) \quad (20)$$

to the original data. If the order of the polynomials $\phi(B)$ and $\theta(B)$ are p and q , respectively, then the model (20) is called an *ARIMA(p, d, q) model* for $\{X_t\}$. If the residuals y_t had been generated by differencing also at some lag greater than 1 to eliminate seasonality, say, for example, $y_t = (1 - B^{12})(1 - B)^d x_t$, and the ARMA model (14) were then fitted to y_t , then the model for the original data would be a more general ARIMA model of the form,

$$\phi(B)(1 - B^{12})(1 - B)^d X_t = \theta(B)Z_t \quad (21)$$

$$\{Z_t\} \sim WN(0, \sigma^2) \quad (22)$$

Selecting and Fitting a Model to Data

In the section titled “Time Series Models”, we discussed two methods for eliminating trend and seasonality with the aim of transforming the original series to a series of residuals suitable for modeling as a zero-mean stationary series. In the section titled “ARMA Processes”, we introduced the class of ARMA models with a wide range of autocorrelation functions. By suitable choice of ARMA parameters,

it is possible to find an ARMA process whose autocorrelations match the sample autocorrelations of the residuals $y_1, y_2, \dots$, up to any specified lag. This is an intuitively appealing and natural approach to the problem of fitting a stationary time series model. However, except when the residuals are truly generated by a purely autoregressive model (i.e., an ARMA($p, 0$) model), this method turns out to give greater large-sample mean squared errors than the method of *maximum Gaussian likelihood* described in the following paragraph.

Suppose for the moment that we know the orders p and q of the ARMA process (equation (14)) that is to be fitted to the residuals $y_1, \dots, y_n$, and suppose that $\beta = (\phi_1, \dots, \phi_p, \theta_1, \dots, \theta_q, \sigma^2)$, is the vector of parameters to be estimated. The Gaussian likelihood $L(\beta; y_1, \dots, y_n)$, is the likelihood computed under the assumption that the joint distribution from which $y_1, \dots, y_n$ are drawn is multivariate normal (see **Maximum Likelihood**). Thus,

$$L(\beta; y_1, \dots, y_n) = (2\pi)^{-n/2} (\det \Gamma_n)^{-1/2} \times \exp \left(-\frac{1}{2} \mathbf{y}_n \Gamma_n^{-1} \mathbf{y}_n \right) \quad (23)$$

where $\mathbf{y}_n = (y_1, \dots, y_n)'$, Γ_n is the matrix of autocovariances $[\gamma(i - j)]_{i,j=1}^n$, and $\gamma(h)$ is the autocovariance function of the model defined by equation (14). Although direct calculation of L is a daunting task, L can be reexpressed in the *innovations form* of Schweppe [4], which is readily calculated from the minimum **mean squared error** one-step linear predictors of the observations and their mean squared errors. These in turn can be readily calculated from the *innovations algorithm* (see [5]).

At first glance, maximization of Gaussian likelihood when the observations appear to be non-Gaussian may seem strange. However, if the noise sequence $\{Z_t\}$ in the model (14) is any independent identically distributed sequence (with finite variance), the large-sample joint distribution of the estimators (assuming the true orders are p and q) is the same as in the Gaussian case (see [5, 6]). This large-sample distribution has a relatively simple Gaussian form that can be used to specify large-sample **confidence intervals** for the parameters (under the assumption that the observations are generated by the fitted model).

Maximization of L with respect to the parameter vector β is a nonlinear optimization problem, requiring the use of an efficient numerical maximization

algorithm. For this reason, a variety of simpler **estimation** methods have been developed. These generally lead to less efficient estimators, which can be used as starting points for the nonlinear optimization. Notable among these are the Hannan–Rissanen algorithm for general ARMA processes, and the Yule–Walker and Burg algorithms for purely autoregressive processes.

The previous discussion assumes that the orders p and q are *known*. However, this is rarely, if ever, the case, and they must be chosen on the basis of the observations. The choice of p and q is referred to as the problem of *order selection*. The shape of the sample autocorrelation function gives some clue as to the order of the ARMA(p, q) model that best represents the data. For example, a sample autocorrelation function that appears to be roughly of the form $\phi^{|h|}$ for some ϕ such that $|\phi| < 1$ suggests (see Example 3) that an AR(1) model might be appropriate, while a sample autocorrelation function that is small in absolute value for lags $h > q$ suggests (see Example 4) that an MA(r) model with $r \leq q$ might be appropriate.

A systematic approach to the problem was suggested by Akaike [7] when he introduced the *information criterion* known as the AIC. He proposed that p and q be chosen by minimizing $AIC(\hat{\beta}(p, q))$, where $\hat{\beta}(p, q)$ is the maximum-likelihood estimator of β for fixed p and q and

$$AIC(\beta) = -2 \ln(L(\beta)) + 2(p + q + 1) \quad (24)$$

The term $2(p + q + 1)$ can be regarded as a *penalty factor* that prevents the selection of excessive values for p and q and the accumulation of additional parameter estimation errors. If the data are truly generated by an ARMA(p, q) model, it has been shown that the AIC criterion tends to overestimate p and q and is not consistent as the sample-size approaches infinity. Consistent estimation of p and q can be obtained by using information criteria with heavier penalty factors such as the Bayesian information criterion (BIC). Since, however, there is rarely a “true” model generating the data, consistency is not necessarily an essential property of order selection methods. It has been shown in [8] that although the AIC criterion does not give consistent estimation of p and q , it is optimal in a certain sense with respect to the prediction of future values of the series. A refined small-sample version of AIC,

known as the AICC, has been developed in [9], and a comprehensive account of model selection can be found in [10].

Having arrived at a potential ARMA model for the data, the model should be checked for goodness of fit to the data. On the basis of the fitted model, the minimum mean squared error linear predictors $\hat{Y}_t$ of each Y_t in terms of Y_s , $s < t$, and the corresponding mean squared errors s_t can be computed (see the section titled “Prediction”). In fact, they are computed in the course of evaluating the Gaussian likelihood in its innovations form. If the fitted model is valid, the properties of the rescaled one-step prediction errors $(Y_t - \hat{Y}_t)/\sqrt{s_t}$ should be similar to those of the sequence Z_t/σ in the model (14), and can, therefore, be used to check the assumed white noise properties of $\{Z_t\}$ and whether the assumption of independence and/or normality is justified. A number of such tests are available (see e.g. [2, Chapter 5]).

Prediction

If $\{Y_t\}$ is a weakly stationary process with mean, $E(Y_t) = \mu$, and autocovariance function, $\text{Cov}(Y_{t+h}, Y_t) = \gamma(h)$, a fundamental property of conditional expectation tells us that the “best” (minimum mean squared error) predictor of Y_{n+h} , $h > 0$, in terms of $Y_1, \dots, Y_n$, is the conditional expectation $E(Y_{n+h} | Y_1, \dots, Y_n)$. However, this depends, in a complicated way, on the joint distributions of the random variables Y_t that are virtually impossible to estimate on the basis of a single series of observations $y_1, \dots, y_n$. However, if the sequence $\{Y_t\}$ is Gaussian, the best predictor of Y_{n+h} in terms of $Y_1, \dots, Y_n$ is a linear function, and can be calculated as described below.

The best *linear* predictor of Y_{n+h} in terms of $\{1, Y_1, \dots, Y_n\}$, that is, the linear combination $P_n Y_{n+h} = a_0 + a_1 Y_1 + \dots + a_n Y_n$, which minimizes the mean squared error, $E[(Y_{n+h} - a_0 - \dots - a_n Y_n)^2]$, is given by

$$P_n Y_{n+h} = \mu + \sum_{i=1}^n a_i (Y_{n+1-i} - \mu) \quad (25)$$

where the vector of coefficients $\mathbf{a} = (a_1, \dots, a_n)'$ satisfies the linear equation,

$$\Gamma_n \mathbf{a} = \boldsymbol{\gamma}_n(h) \quad (26)$$

with $\mathbf{y}_n(h) = (\gamma(h), \gamma(h+1), \dots, \gamma(h+n-1))$ and $\Gamma_n = [\gamma(i-j)]_{i,j=1}^n$. The mean squared error of the best linear predictor is

$$E(Y_{n+h} - P_n Y_{n+h})^2 = \gamma(0) - \mathbf{a}' \mathbf{y}_n(h) \quad (27)$$

Once a satisfactory model has been fitted to the sequence $y_1, \dots, y_n$, it is, therefore, a straightforward but possibly tedious matter to compute best linear predictors of future observations by using the mean and autocovariance function of the fitted model and solving the linear equations for the coefficients $a_0, \dots, a_n$. If n is large, then the set of linear equations for $a_0, \dots, a_n$ is large, and, so, recursive methods using the Levinson–Durbin algorithm or the innovations algorithm have been devised to express the solution for $n = k+1$ in terms of the solution for $n = k$, and, hence, to avoid the difficulty of inverting large matrices. For details see, for example [2, Chapter 2].

If an ARMA model is fitted to the data, the special linear structure of the ARMA process arising from the defining equations can be used to greatly simplify the calculation of the best linear h -step predictor $P_n Y_{n+h}$ and its mean squared error, $\sigma_n^2(h)$. If the fitted model is Gaussian, we can also compute 95% prediction bounds, $P_n Y_{n+h} \pm 1.96\sigma_n(h)$. For details see, for example [2, Chapter 5].

Example 5 In order to predict future values of the causal AR(1) process defined in Example 3, we can make use of the fact that linear prediction is a linear operation, and that $P_n Z_t = 0$ for $t > n$ to deduce that

$$\begin{aligned} P_n Y_{n+h} &= \phi P_n Y_{n+h-1} = \phi^2 P_n Y_{n+h-2} = \dots \\ &= \phi^h Y_n, \quad h \geq 1 \end{aligned} \quad (28)$$

In order to obtain forecasts and prediction bounds for the *original* series that were transformed to generate the residuals, we simply apply the inverse transformations to the forecasts and prediction bounds for the residuals.

The Frequency Viewpoint

The methods described so far are referred to as *time-domain methods* since they focus on the evolution in time of the sequence of random variables $X_1, X_2, \dots$ representing the observed data. If, however, we regard the sequence as a random function defined on the integers, then an alternative

approach is to consider the decomposition of that function into sinusoidal components, analogous to the Fourier decomposition of a deterministic function. This approach leads to the *spectral representation* of the sequence $\{X_t\}$, according to which every weakly stationary sequence has a representation

$$X_t = \int_{-\pi}^{\pi} e^{i\omega t} dZ(t) \quad (29)$$

where $\{Z(t), -\pi \leq t \leq \pi\}$ is a process with uncorrelated increments. A detailed discussion of this approach can be found, for example, in [5, 11, 12], but is outside the scope of this article. Intuitively, however, the expression (29) can be regarded as representing the random function $\{X_t, t = 0, \pm 1, \pm 2, \dots\}$ as the limit of a linear combination of sinusoidal functions with uncorrelated random coefficients. The analysis of weakly stationary processes by means of their spectral representation is referred to as *frequency-domain analysis* or *spectral analysis*. It is equivalent to time-domain analysis, but provides an alternative way of viewing the process, which, for some applications, may be more illuminating. For example, in the design of a structure subject to a randomly fluctuating load, it is important to be aware of the presence in the loading force of a large sinusoidal component with a particular frequency in order to ensure that this is not a resonant frequency of the structure.

Multivariate Time Series

Many time series arising in practice are best analyzed as components of some vector-valued (multivariate) time series $\{\mathbf{X}_t\} = (X_{t1}, \dots, X_{tm})'$ in which each of the component series $\{X_{ti}, t = 1, 2, 3, \dots\}$ is a univariate time series of the type already discussed. In multivariate time series modeling, the goal is to account for, and take advantage of, the dependence not only between observations of a single component at different times, but also between the different component series. For example, if X_{t1} is the daily percentage change in the closing value of the Dow–Jones Industrial Average in New York on trading day t , and if X_{t2} is the analog for the Australian All-Ordinaries index (see Example 2), then $\{\mathbf{X}_t\} = (X_{t1}, X_{t2})'$ is a bivariate time series in which there is very little evidence of autocorrelation in either of the two component series. However, there is strong evidence

of **correlation** between X_{t1} and $X_{(t+1)2}$, indicating that the Dow–Jones percentage change on day t is of value in predicting the All-Ordinaries percentage change on day $t + 1$. Such dependencies in the multivariate case can be measured by the **covariance** matrices,

$$\Gamma(t + h, t) = [\text{cov}(X_{(t+h),i}, X_{t,j})]_{i,j=1}^m \quad (30)$$

where the number of components, m , is two in this particular example. Weak stationarity of the multivariate series $\{\mathbf{X}_t\}$ is defined, as in the univariate case, to mean that all components have finite second **moments** and that the mean vectors $E(\mathbf{X}_t)$ and covariance matrices $\Gamma(t + h, t)$ are independent of t .

Much of the analysis of multivariate time series is analogous to that of univariate series, multivariate ARMA (or VARMA) processes being defined again by linear equations of the form (14) but with vector-valued arguments, and matrix coefficients. There are, however, some new important considerations arising in the multivariate case. One is the question of VARMA nonidentifiability. In the univariate case, an $\text{AR}(p)$ process cannot be reexpressed as a finite-order moving average process. However, this is not the case for $\text{VAR}(p)$ processes. There are simple examples of $\text{VAR}(1)$ processes that are also $\text{VMA}(1)$ processes. This lack of identifiability, together with the large number of parameters in a VARMA model and the complicated shape of the likelihood surface, introduces substantial additional difficulty into maximum Gaussian likelihood estimation for VARMA processes. Restricting attention to VAR processes eliminates the identifiability problem. Moreover, the fitting of a $\text{VAR}(p)$ process by equating covariance matrices up to lag p is asymptotically efficient and simple to implement using a multivariate version of the Levinson–Durbin algorithm (see [13, 14]).

For nonstationary univariate time series, we discussed in the section titled “Objectives” the use of differencing to transform the data to residuals suitable for modeling as zero-mean stationary series. In the multivariate case, the concept of *cointegration*, due to Granger [15], plays an important role in this connection. The m -dimensional vector time series $\{\mathbf{X}_t\}$ is said to be integrated of order d (or $I(d)$) if, when the difference operator ∇ is applied to each component $d - 1$ times, the resulting process is nonstationary, while if it is applied d times, the resulting series is stationary. The $I(d)$ process $\{\mathbf{X}_t\}$

is said to be cointegrated with cointegration vector $\boldsymbol{\alpha}$, if $\boldsymbol{\alpha}$ is an $m \times 1$ vector such that $\{\boldsymbol{\alpha}'\mathbf{X}_t\}$ is of order less than d . Cointegrated processes arise naturally in economics. Engle and Granger [16] give, as an illustrative example, the vector of tomato prices in northern and southern California (say X_{t1} and X_{t2} , respectively). These are linked by the fact that if one were to increase sufficiently relative to the other, the profitability of buying in one market and selling in the other would tend to drive the prices together, suggesting that although the two series separately may be nonstationary, the difference varies in a stationary manner. This corresponds to having a cointegration vector $\boldsymbol{\alpha} = (1, -1)'$. Statistical inference for multivariate models with cointegration is discussed in [17].

State-Space Models

State-space models and the associated Kalman recursions have had a profound impact on time series analysis. A linear state-space model for a (possibly multivariate) time series $\{\mathbf{Y}_t, t = 1, 2, \dots\}$ consists of two equations. The first, known as the *observation equation*, expresses the w -dimensional observation vector $\mathbf{Y}_t$ as a linear function of a v -dimensional state variable $\mathbf{X}_t$ plus noise. Thus,

$$\mathbf{Y}_t = \mathbf{G}_t \mathbf{X}_t + \mathbf{W}_t, \quad t = 1, 2, \dots \quad (31)$$

where $\{\mathbf{W}_t\}$ is a sequence of uncorrelated random vectors with $E(\mathbf{W}_t) = \mathbf{0}$, $\text{cov}(\mathbf{W}_t) = \mathbf{R}_t$, and $\{\mathbf{G}_t\}$ is a sequence of $w \times v$ matrices. The second equation, called the *state equation*, determines the state $\mathbf{X}_{t+1}$ at time $t + 1$ in terms of the previous state $\mathbf{X}_t$ and a noise term. The state equation is

$$\mathbf{X}_{t+1} = \mathbf{F}_t \mathbf{X}_t + \mathbf{V}_t, \quad t = 1, 2, \dots \quad (32)$$

where $\{\mathbf{F}_t\}$ is a sequence of $v \times v$ matrices, $\{\mathbf{V}_t\}$ is a sequence of uncorrelated random vectors with $E(\mathbf{V}_t) = \mathbf{0}$, $\text{cov}(\mathbf{V}_t) = \mathbf{Q}_t$, and $\{\mathbf{V}_t\}$ is uncorrelated with $\{\mathbf{W}_t\}$ (i.e., $E(\mathbf{W}_t \mathbf{V}_s') = \mathbf{0}$ for all s and t). To complete the specification, it is assumed that the initial state $\mathbf{X}_1$ is uncorrelated with all of the noise terms $\{\mathbf{V}_t\}$ and $\{\mathbf{W}_t\}$.

An extremely rich class of models for time series, including and going well beyond the ARIMA models described earlier, can be formulated within this framework (see [18]). In econometrics, the structural time series models developed in [19], in which

trend and seasonal components are allowed to evolve randomly, also fall into this framework. The power of the state-space formulation of time series models depends heavily on the Kalman recursions, which allow best linear predictors and best linear estimates of various model-related variables to be computed in a routine way. Time series with missing values are also readily handled in the state-space framework.

More general state-space models, in which the linear relationships (31) and (32) are replaced by the specification of conditional distributions, are also widely used to generate an even broader class of models, including, for example, models for time series of counts such as the numbers of reported new cases of a particular disease (see e.g. [20]).

Additional Topics

Although linear models for time series data have found broad applications in many areas of the physical, biological, and engineering sciences, there are also many areas where they have been found inadequate. Consequently, a great deal of attention has been devoted to the development of nonlinear models for such applications. These include threshold models, [21]; bilinear models, [22]; random-coefficient autoregressive models, [23]; Markov switching models, [24]; and many others. For financial time series, the ARCH (autoregressive conditionally heteroscedastic) model of Engle [25], and its generalized version, the Generalized Autoregressive Conditionally Heteroscedastic (GARCH) model of Bollerslev [26], have been particularly successful in modeling financial-returns data of the type illustrated in Figure 4.

Although the sample autocorrelation function of the series shown in Figure 4 is compatible with the hypothesis that the series is an independent and identically distributed white noise sequence, the sample autocorrelation functions of the absolute values and the squares of the series are significantly different from zero, contradicting the hypothesis of independence. ARCH and GARCH processes are white noise sequences that are nevertheless dependent. The dependence is introduced in such a way that these models exhibit many of the distinctive features (heavy-tailed marginal distributions and persistence of volatility) that are observed in financial time series.

The recent explosion of interest in the modeling of financial data, in particular, with a view to solving option-pricing and asset allocation problems, has led to a great deal of interest, not only in ARCH and GARCH models, but also to stochastic volatility models and to models evolving continuously in time. For a recent account of time series models specifically related to financial applications, see [27].

Apart from their importance in finance, continuous-time models provide a very useful framework for the modeling and analysis of discrete-time series with irregularly spaced data or missing observations. For such applications, see [28].

Parametric Tests

Introduction

One way to look at the definition of a parametric test is to note that a parameter is a measure taken from a population. Thus, the mean and standard deviation of data for a whole population are both parameters. Parametric tests make certain assumptions about the nature of parameters, including the appropriate probability distribution, which can be used to decide whether the result of a statistical test would be significant. In addition, they can be used to find a **confidence interval** for a given parameter.

The types of tests given here have been categorized into those that compare means, those that compare variances, those that relate to **correlation** and regression, and those that deal with frequencies and proportions.

Comparing Means

z-Tests

z-tests compare a statistic (or single score) from a sample with the expected value of that statistic in the population under the null hypothesis. The expected value of the statistic under H_0 is subtracted from the observed value of the statistic and the result is divided by its standard deviation. When the sample statistic is based on more than a single score, then the standard deviation for that statistic is its standard error (*see* **Standard Error**). Thus, this type of test can only be used when the expected value of the statistic and its standard deviation are known. The probability of a *z*-value is found from the standardized **normal distribution**, which has a mean of zero and a standard deviation of one (*see* **Probability Density Functions**).

One-Group *z*-Test for a Single Score. In this version of the test, the equation is

$$z = \frac{x - \mu}{\sigma} \quad (1)$$

where

x is the single score
 μ is the mean for the scores in the population
 σ is the standard deviation of the population.

Example 1

Single score = 10

$$\mu = 5$$

$$\sigma = 2$$

$$z = \frac{10 - 5}{2} = 2.5.$$

Critical value for z at $\alpha = 0.05$ with a two-tailed test is 1.96.

Decision: reject H_0 .

One-Group *z*-Test for a Single Mean. This version of the test is a modification of the previous one because the distribution of means is the standard error of the mean: $\sigma/\sqrt{n}$, where n is the sample size.

The equation for this *z*-test is

$$z = \frac{m - \mu}{\left(\frac{\sigma}{\sqrt{n}}\right)} \quad (2)$$

where

m is the mean of the sample
 μ is the mean of the population
 σ is the standard deviation of the population
 n is the **sample size**.

Example 2

$$m = 5.5$$

$$\mu = 5$$

$$\sigma = 2$$

$$n = 20$$

$$z = \frac{5.5 - 5}{\left(\frac{2}{\sqrt{20}}\right)} = 1.12.$$

The critical value for z with $\alpha = 0.05$ and a one-tailed test is 1.64.

Decision: fail to reject H_0 .

2 Parametric Tests

t-Tests

t-tests form a family of tests that derive their probability from Student's *t* distribution (see **Probability Density Functions**). The shape of a particular *t* distribution is a function of the **degrees of freedom**. *t*-tests differ from *z*-tests in that they estimate the population standard deviation from the standard deviation(s) of the sample(s). Different versions of the *t*-test have different ways in which the degrees of freedom are calculated.

One-Sample *t*-Test. This test is used to compare a mean from a sample with that of a population or a hypothesized value from the population, when the standard deviation for the population is not known. The null hypothesis is that the sample is from the (hypothesized) population (that is, $\mu = \mu_h$, where μ is the mean of the population from which the sample came and μ_h is the mean of the population with which it is being compared).

The equation for this version of the *t*-test is

$$t = \frac{m - \mu_h}{\left(\frac{s}{\sqrt{n}}\right)} \quad (3)$$

where

- m is the mean of the sample
- μ_h is the mean or assumed mean for the population
- s is the standard deviation of the sample
- n is the sample size.

Degrees of freedom

In this version of the *t*-test, $df = n - 1$.

Example 3

$$\begin{aligned} m &= 9, \mu_h = 7 \\ s &= 3.2, n = 10 \\ df &= 9 \\ t_{(9)} &= 1.98. \end{aligned}$$

The critical *t* with $df = 9$ at $\alpha = 0.05$ for a two-tailed test is 2.26.

Decision: fail to reject H_0 .

Two-Samples *t*-Test. This test is used to compare the means of two different samples. The null hypothesis is $\mu_1 = \mu_2$ (i.e., $\mu_1 - \mu_2 = 0$, where μ_1 and μ_2

are the means of the two populations from which the samples come).

There are two versions of the equation for this test – one when the variances of the two populations are homogeneous (see **Homogeneity of Variances**) and the variances are pooled, and one when the variances are heterogeneous and are entered separately into the equation.

Homogeneous variance

$$t = \frac{m_1 - m_2}{\sqrt{pv \times \left(\frac{1}{n_1} + \frac{1}{n_2}\right)}} \quad (4)$$

where m_1 and m_2 are the sample means of groups 1 and 2 respectively, n_1 and n_2 are the sample sizes of the two groups, and pv is the **pooled variance**

$$pv = \frac{(n_1 - 1) \times s_1^2 + (n_2 - 1) \times s_2^2}{n_1 + n_2 - 2} \quad (5)$$

where s_1^2 & s_2^2 are the variances of groups 1 and 2. When the two group sizes are the same, this simplifies to

$$t = \frac{m_1 - m_2}{\sqrt{\frac{s_1^2 + s_2^2}{n}}} \quad (6)$$

where n is the sample size of each group.

Heterogeneous variances

$$t = \frac{m_1 - m_2}{\sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}} \quad (7)$$

Degrees of freedom

Homogeneous variance

$$df = n_1 + n_2 - 2 \quad (8)$$

Heterogeneous variance

$$df = \frac{\left(\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}\right)^2}{\frac{\left(\frac{s_1^2}{n_1}\right)^2}{n_1 - 1} + \frac{\left(\frac{s_2^2}{n_2}\right)^2}{n_2 - 1}} \quad (9)$$

Example 4 Groups with homogeneous variance

$$m_1 = 5.3, m_2 = 4.1$$

$$\begin{aligned}
n_1 &= n_2 = 20 \\
s_1^2 &= 1.3, s_2^2 = 1.5 \\
df &= 38 \\
t_{(38)} &= 3.21.
\end{aligned}$$

The critical t for a two-tailed probability with $df = 38$, at $\alpha = 0.05$ is 2.02.

Decision: reject H_0 .

Paired t -Test. This version of the t -test is used to compare two means that have been gained from the same sample, for example, quality of products before and after a corrective action is applied to them, or from two matched samples. For each product, a difference score is found between the two scores for that product (quality after the correction minus the quality before). The null hypothesis is that the mean of the difference scores is zero ($\mu_d = 0$, where μ_d is the mean of the difference scores in the population).

The equation for this test is

$$t = \frac{m_d}{\left(\frac{s_d}{\sqrt{n}}\right)} \quad (10)$$

where

- m_d is the mean of the difference scores
- s_d is the standard deviation of the difference scores
- n is the number of difference scores.

Degrees of freedom

In this version of the t -test, the df are $n - 1$.

Example 5

$$\begin{aligned}
m_1 &= 153.2, m_2 = 145.1, m_d = 8.1 \\
s_d &= 14.6, n = 20 \\
df &= 19 \\
t_{(19)} &= 2.48.
\end{aligned}$$

The critical t for $df = 19$ at $\alpha = 0.05$ for a one-tailed probability is 1.729.

Decision: reject H_0 .

ANOVA

Analysis of variance (ANOVA) (see **Analysis of Variance**) allows the comparison of the means of

more than two different conditions to be compared at the same time in a single omnibus test. As an example, researchers might wish to study differences in productivity of shifts. The null hypothesis, which is tested, is that the mean productivity is equal for all shifts. Thus, the null hypothesis would be $\mu_1 = \mu_2 = \mu_3$, where the μ_i denote the mean daily productivity of the morning, evening, and night shifts. ANOVA partitions the overall variance in a set of data into different parts.

The statistic that is created from an ANOVA is the F -ratio. It is the ratio of an estimate of the variance between groups and an estimate of the variance, which is not explicable in terms of differences between groups, that which is due to individual differences (sometimes referred to as *error*).

$$F = \frac{\text{variance between groups}}{\text{variance due to individual differences}} \quad (11)$$

If the null hypothesis is true, then these two variance estimates will both be due to individual differences and F will be close to 1. If the values from the different groups do differ, then F will tend to be larger than 1. The probability of an F -value is found from the F distribution (see **Probability Density Functions**). The value of F , which is statistically significant, depends on the degrees of freedom. In this test, there are two different degrees of freedom that determine the shape of the F distribution: the df for the variance between groups and the df for the error.

The variance estimates are usually termed the *mean squares (MS)*. These are formed by dividing a sum of squared deviations from a mean (usually referred to as the **sum of squares**) by the appropriate degrees of freedom.

The F -ratio is formed in different ways, depending on aspects of the design. In addition, the F -value will be calculated on a different basis if the independent variables (IVs) are fixed or random. The examples given here are for fixed IVs. For variations on the calculations, see [1]. The methods of calculation shown will be ones designed to explicate what the equation is doing rather than the computationally simplest version.

One-Way ANOVA

This version of the test partitions the total variance into two components: between groups (attributed to the IV) and within groups (the error).

4 Parametric Tests

Sums of squares

The sum of squares between the groups (SS_{bg}) is formed from

$$SS_{bg} = \sum [n_i \times (m_i - m)^2] \quad (12)$$

where

n_i is the sample size in group i

m_i is the mean of group i

m is the overall mean.

The sum of squares within the groups (SS_{wg}) is formed from

$$SS_{wg} = \sum \sum (x_{ij} - m_i)^2 \quad (13)$$

where

x_{ij} is the j th data point in group i

m_i is the mean of group i .

Degrees of freedom

The df for between groups is one fewer than the number of groups:

$$df_{bg} = k - 1 \quad (14)$$

where k is the number of groups.

The degrees of freedom for within groups is the total sample size minus the number of groups:

$$df_{wg} = N - k \quad (15)$$

where

N is the total sample size

k is the number of groups

Mean squares

The MS are formed by dividing the sum of squares by the appropriate degrees of freedom:

$$MS_{bg} = \frac{SS_{bg}}{df_{bg}} \quad (16)$$

$$MS_{wg} = \frac{SS_{wg}}{df_{wg}} \quad (17)$$

F-ratio

The F -ratio is formed by

$$F = \frac{MS_{bg}}{MS_{wg}} \quad (18)$$

Example 6 Three groups each with six observations are compared (Table 1).

$$\text{Overall mean}(m) = 4.278$$

$$SS_{bg} = \sum [6 \times (m_i - 4.278)^2] = 40.444$$

$$SS_{wg} = 19.167$$

$$df_{bg} = 3 - 1 = 2$$

$$df_{wg} = 18 - 3 = 15$$

$$MS_{bg} = \frac{40.444}{2} = 20.222$$

$$MS_{wg} = \frac{19.167}{15} = 1.278$$

$$F_{(2,15)} = \frac{20.222}{1.278} = 15.826.$$

The critical F -value for $\alpha = 0.05$, with df of 2 and 15 is 3.68.

Decision: reject H_0 .

Multiway ANOVA

When there is more than one IV, the way in which these variables work together can be investigated to see whether some act as moderators for others. An example of a design with two IVs would be if researchers wanted to test whether the effects of different types of music (jazz, classical, or pop) on blood pressure might vary, depending on the age of the listeners. The moderating effects of age on the effects of music might be indicated by an interaction between age and music type. In other words, the pattern of the link between blood pressure and music type differed between the two age groups. Therefore,

Table 1 Observations and group means in a one-way design

	Group		
	A	B	C
	2	5	7
	3	7	5
	3	5	6
	3	5	4
	1	5	4
	1	4	7
Mean (m_i)	2.167	5.167	5.500

an ANOVA with two IVs will have three F -ratios, each of which is testing a different null hypothesis. The first will ignore the presence of the second IV and test the main effect of the first IV, such that if there were two conditions in the first IV, then the null hypothesis would be $\mu_1 = \mu_2$, where μ_1 and μ_2 are the means in the two populations for the first IV. The second F -ratio would test the second null hypothesis, which would refer to the **main effect** of the second IV with the existence of the first being ignored. Thus, if there were two conditions in the second IV, then the second H_0 would be $\mu_a = \mu_b$ where μ_a and μ_b are the means in the population for the second IV. The third F -ratio would address the third H_0 , which would relate to the interaction between the two IVs. When each IV has two levels, the null hypothesis would be $\mu_{a1} - \mu_{a2} = \mu_{b1} - \mu_{b2}$, where the μ_{a1} denotes the mean for the combination of the first condition of the first IV and the first condition of the second IV.

Examples are only given here of ANOVAs with two IVs. For more complex designs, there will be higher-order interactions as well. When there are k IVs, there will be 2-, 3-, 4-, ..., k -way interactions, which can be tested. For details of such designs, see [1].

This version of ANOVA partitions the overall variance into four parts: the main effect of the first IV, the main effect of the second IV, the interaction between the two IVs, and the error term, which is used in all three F -ratios.

Sums of squares

The total sum of squares (SS_{Total}) is calculated from

$$SS_{\text{Total}} = \sum \sum \sum (x_{ijp} - m)^2 \quad (19)$$

where x_{ijp} is the p th observation where IV_1 is on level i , and IV_2 is on level j . A simpler description is that it is the sum of the squared deviations of each observation from the overall mean.

The sum of squares for the first IV (SS_A) is calculated from

$$SS_A = \sum [n_i \times (m_i - m)^2] \quad (20)$$

where

n_i is the number of observations having level i for IV_1

m_i is the mean of the observations having level i for IV_1
 m is the overall mean.

The sum of squares for the second IV (SS_B) is calculated from

$$SS_B = \sum [n_j \times (m_j - m)^2] \quad (21)$$

where

n_j is the number of observations having level j for IV_2
 m_j is the mean of the observations having level j for IV_2
 m is the overall mean.

The interaction sum of squares (SS_{AB}) can be found by finding the between-cells sum of squares ($SS_{\text{b.cells}}$), where a cell refers to the combination of levels in the two IVs: for example, first level of IV_1 and first level of IV_2 . $SS_{\text{b.cells}}$ is found from

$$SS_{\text{b.cells}} = \sum \sum [n_{ij} \times (m_{ij} - m)^2] \quad (22)$$

where

n_{ij} is the number of observations for which IV_1 is on level i and IV_2 is on level j ,
 m_{ij} is the mean of the observations for which IV_1 is on level i and IV_2 is on level j ,
 m is the overall mean.

$$SS_{AB} = SS_{\text{b.cells}} - (SS_A + SS_B) \quad (23)$$

The sum of squares for the residual (SS_{res}) can be found from

$$SS_{\text{res}} = SS_{\text{Total}} - (SS_A + SS_B + SS_{AB}) \quad (24)$$

Degrees of freedom

The total degrees of freedom (df_{Total}) are found from

$$df_{\text{Total}} = N - 1 \quad (25)$$

where N is the total sample size.

The degrees of freedom for each main effect (for example, df_A) are found from

$$df_A = k - 1 \quad (26)$$

where k is the number of levels in that IV.

6 Parametric Tests

The interaction degrees of freedom (df_{AB}) are found from

$$df_{AB} = df_A \times df_B \quad (27)$$

where df_A and df_B are the degrees of freedom of the two IVs.

The degrees of freedom for the residual (df_{res}) are calculated from

$$df_{res} = df_{Total} - (df_A + df_B + df_{AB}) \quad (28)$$

Mean squares

Each mean square is found by dividing the sum of squares by the appropriate df. For example, the mean square for the interaction (MS_{AB}) is found from

$$MS_{AB} = \frac{SS_{AB}}{df_{AB}} \quad (29)$$

F-ratios

Each F -ratio is found by dividing a given mean square by the mean square for the residual. For example, the F -ratio for the interaction is found from

$$F = \frac{MS_{AB}}{MS_{res}} \quad (30)$$

Example 7 Twenty observations are collected, equally distributed over the four combinations of two factors, each having two levels (Table 2). Overall mean = 8.2

Sums of squares

$$SS_{Total} = 139.2$$

$$SS_A = 51.2$$

$$SS_B = 5.0$$

$$SS_{b,cells} = 56.4$$

$$SS_{AB} = 56.4 - (51.2 + 5.0) = 0.2$$

$$SS_{res} = 139.2 - (51.2 + 5.0 + 0.2) = 82.8$$

Degrees of freedom

$$df_{Total} = 20 - 1 = 19$$

$$df_A = 2 - 1 = 1$$

$$df_B = 2 - 1 = 1$$

$$df_{AB} = 1 \times 1 = 1$$

$$df_{res} = 19 - (1 + 1 + 1) = 16$$

Table 2 Observations in a two-way design

IV ₁ (A)	1		2	
IV ₂ (B)	1	2	1	2
	9	7	6	4
	11	10	4	4
	10	14	9	10
	10	10	5	9
	7	10	6	9
Means	9.4	10.2	6	7.2

Mean squares

$$MS_A = \frac{51.2}{1} = 51.2$$

$$MS_B = \frac{5}{1} = 5$$

$$MS_{AB} = \frac{0.2}{1} = 0.2$$

$$MS_{res} = \frac{82.8}{16} = 5.175$$

F-ratios

$$F_{A(1,16)} = \frac{51.2}{5.175} = 9.89$$

The critical value for F at $\alpha = 0.05$ with df of 1 and 16 is 4.49.

Decision: reject H_0

$$F_{B(1,16)} = \frac{5}{5.175} = 0.97$$

Decision: fail to reject H_0

$$F_{AB(1,16)} = \frac{0.2}{5.175} = 0.04$$

Decision: fail to reject H_0 .

Extensions of ANOVA. ANOVA can be extended in a number of ways, including multiple factors, random and fixed factors, crossed and nested designs, and multivariate responses. See [1] for a general description.

Comparing Variances

F-Test for Difference between Variances

Two Independent Variances. This test compares two variances from different samples to see whether they are significantly different. An example of its use could be where we want to see whether the variability

in quality of one production line differs from the variability at another line.
The equation for the F -test is

$$F = \frac{s_1^2}{s_2^2} \quad (31)$$

where the sample variance in one sample is divided by the variance in the other sample.

If the research hypothesis is that one particular group will have the larger variance, then that should be treated as group 1 in this equation. As usual, an F -ratio close to 1 would suggest no difference in the variances of the two groups. A large F -ratio would suggest that group 1 has a larger variance than group 2, but it is worth noting that a particularly small F -ratio, and therefore a probability close to 1, would suggest that group 2 has the larger variance.

Degrees of freedom

The degrees of freedom for each variance are one fewer than the sample size in that group.

Example 8

Group 1
Variance: 16
Sample size: 100

Group 2
Variance: 11
Sample size: 150
 $F = \frac{16}{11} = 1.455$

Degrees of freedom

Group 1 $df = 100 - 1 = 99$; group 2 $df = 150 - 1 = 149$

The critical value of F with df of 99 and 149 for $\alpha = 0.05$ is 1.346.

Decision: reject H_0 .

k Independent Variances. The following procedure was devised by Bartlett [2] to test differences between the variances from more than two independent groups $i = 1, \dots, k$.

The finding of the statistic B (which can be tested with the χ^2 distribution) involves a number of stages. The first stage is to find an estimate of the overall variance (S^2). This is achieved by multiplying each sample variance by its related df , which is one fewer

than the size of that sample, summing the results and dividing that sum by the sum of all the df :

$$S^2 = \frac{\sum [(n_i - 1) \times s_i^2]}{N - k} \quad (32)$$

where

n_i is the sample size for the i th group
 s_i^2 is the sample variance in group i
 N is the total sample size
 k is the number of groups.

Next, we need to calculate a statistic known as C , using

$$C = 1 + \frac{1}{3 \times (k - 1)} \times \left[\sum \left(\frac{1}{n_i - 1} \right) - \frac{1}{N - k} \right] \quad (33)$$

We are now in a position to calculate B :

$$B = \frac{2.3026}{C} \times \left[(N - k) \times \log(S^2) - \sum \{ (n_i - 1) \times \log(s_i^2) \} \right] \quad (34)$$

where $\log$ means taking logarithm to the base 10.

Degrees of freedom

$$df = k - 1, \quad \text{where } k \text{ is the number of groups} \quad (35)$$

Kanji [3] cautions against using the chi-square distribution when the sample sizes are smaller than 6 and provides a table of critical values for a statistic derived from B when this is the case.

Example 9 We wish to compare the variances of three groups: 2.62, 3.66, and 2.49, with each group having the same sample size of 10.

$$\begin{aligned} N &= 30, k = 3, N - k = 27, C = 0.994 \\ S^2 &= 2.923, \log(s_1^2) = 0.418, \log(s_2^2) = 0.563, \\ \log(s_3^2) &= 0.396 \\ \log(S^2) &= 0.466, \\ (N - k) \times \log(S^2) &= 12.579 \\ \sum [(n_i - 1) \times \log(s_i^2)] &= 12.402 \\ B &= 0.4098 \\ df &= 3 - 1 = 2 \end{aligned}$$

8 Parametric Tests

The critical value of χ^2 for $\alpha = 0.05$ for $df = 2$ is 5.99.

Decision: fail to reject H_0 .

Correlation and Regression

***t*-Test for a Single Correlation Coefficient.** This test can be used to test the statistical significance of a correlation (*see Correlation*) between two variables. It makes the assumption under the null hypothesis that there is no correlation between these variables in the population. Therefore, the null hypothesis is $\rho = 0$, where ρ is the correlation in the population.

The equation for this test is

$$t = \frac{r \times \sqrt{n-2}}{\sqrt{1-r^2}} \quad (36)$$

where

r is the correlation in the sample
 n is the sample size

Degrees of freedom

In this version of the *t*-Test, $df = n - 2$, where n is the sample size.

Example 10

$$\begin{aligned} r &= 0.4, n = 15 \\ df &= 13 \\ t_{(13)} &= 1.57. \end{aligned}$$

Critical t for a two-tailed test with $\alpha = 0.05$ and $df = 13$ is 2.16.

Decision: fail to reject H_0 .

***t*-Test for Regression Coefficient.** This tests the size of an unstandardized regression coefficient. In the case of simple regression, where there is only one predictor variable, the null hypothesis is that the regression in the population is 0; that is, that the variance in the predictor variable does not account for any of the variance in the criterion variable. In multiple linear regression, the null hypothesis is that the predictor variable does not account for any variance in the criterion variable, which is not accounted for by the other predictor variables.

The version of the *t*-test is

$$t = \frac{b}{SE} \quad (37)$$

where b is the unstandardized regression coefficient
 SE is the standard error for the regression coefficient.
 In simple regression, the standard error is found from

$$SE = \sqrt{\frac{MS_{\text{res}}}{SS_p}} \quad (38)$$

where MS_{res} is the MS of the residual for the regression

SS_p is the sum of squares for the predictor variable.

For multiple regression, the standard error takes into account the interrelationship between the predictor variable for which the SE is being calculated and the other predictor variables in the regression (see [4]).

Degrees of freedom

The degrees of freedom for this version of the *t*-test are based on p (the number of predictor variables) and n (the sample size): $df = n - p - 1$.

Example 11 In a simple regression ($p = 1$), $b = 1.3$, and the standard error of the regression coefficient is 0.5

$$\begin{aligned} n &= 30 \\ df &= 28 \\ t_{(28)} &= 2.6 \end{aligned}$$

The critical value for t with $df = 28$, for a two-tailed test with $\alpha = 0.05$ is 2.048.

Decision: reject H_0 .

In multiple regression, it can be argued that a correction to α should be made to allow for multiple testing. This could be achieved by using a Bonferroni adjustment.

***F*-Test for a Single R^2 .** This is the equivalent of a one-way ANOVA. In this case, the overall variance within the variable to be predicted (the response variable, for example, moisture percentage) is separated into two sources: that which can be explained by the relationship between the predictor variable(s) (such as various

machine settings) and the response variable, and that which cannot be explained by this relationship, the residual.

The equation for this F -test is

$$F = \frac{(N - p - 1) \times R^2}{(1 - R^2) \times p} \quad (39)$$

where N is the sample size

p is the number of predictor variables

R^2 is the squared multiple correlation coefficient (see **Coefficient of Determination (R^2)**).

Degrees of freedom

The regression degrees of freedom are p (the number of predictor variables). The residual degrees of freedom are $N - p - 1$.

Example 12 Number of predictor variables: 3

Sample size: 336

Regression df : 3

Residual df : 332

$$R^2 = 0.03343$$

$$F_{(3,332)} = \frac{(336 - 3 - 1) \times 0.03343}{(1 - 0.03343) \times 3} = 3.83$$

Critical F -value with df of 3 and 332 for $\alpha = 0.05$ is 2.63.

Decision: reject H_0 .

F -Test for Comparison of Two R^2 . This tests whether the addition of predictor variables to an existing regression model adds significantly to the amount of variance that the model explains. If only one variable is being added to an existing model, then the information about whether it adds significantly is already supplied by the t -test for the regression coefficient of the newly added variable.

The equation for this F -test is

$$F = \frac{(N - p_1 - 1) \times (R_1^2 - R_2^2)}{(p_1 - p_2) \times (1 - R_1^2)} \quad (40)$$

where N is the sample size.

The subscript 1 refers to the regression with more predictor variables and subscript 2, the regression with fewer predictor variables.

p is the number of predictor variables.

R^2 is the squared multiple correlation coefficient from a regression.

Degrees of freedom

The regression $df = p_1 - p_2$, while the residual $df = N - p_1 - 1$.

Example 13 $R_1^2 = 0.047504$

Number of predictor variables (p_1): 5

$R_2^2 = 0.03343$

Number of predictor variables (p_2): 3

Total sample size: 336

df for regression = $5 - 3 = 2$

df for residual = $336 - 5 - 1 = 330$

$F_{(2,330)} = 2.238$.

The critical value of F with df of 2 and 330 for $\alpha = 0.05$ is 3.023.

Decision: fail to reject H_0 .

Frequencies and Proportions

Chi-Square

χ^2 is a distribution against which the results of a number of statistical tests are compared. The two most frequently used tests that use this distribution are themselves called χ^2 tests and are used when the data take the form of frequencies. Both types involve the comparison of frequencies that have been found (observed) to fall into particular categories with the frequencies that could be expected if the null hypothesis were correct. The categories have to be mutually exclusive; that is, a case cannot appear in more than one category.

The first type of test involves comparing the frequencies in each category for a single variable, for example, the number of smokers and nonsmokers in a sample. It has two variants, which have a different way of viewing the null **hypothesis testing** process. One version is like the example given above, and might have the null hypothesis that the number of smokers in the population is equal to the number of nonsmokers. However, the null hypothesis does not have to be that the frequencies are equal; it could be that they divide the population into particular proportions, for example, 0.4 of the population are smokers and 0.6 are nonsmokers.

The second way in which this test can be used is to test whether a set of data is distributed

in a particular way, for example, that they form a normal distribution. Here, the expected proportions in different intervals are derived from the proportions of a normal curve, with the observed mean and standard deviation, that would lie in each interval, and H_0 is that the data are normally distributed.

The second most frequent χ^2 test is for contingency tables where two variables are involved, for example, the number of smokers and nonsmokers in two different socioeconomic groups.

All the tests described here are calculated in the following way:

$$\chi^2 = \sum \frac{(f_o - f_e)^2}{f_e} \quad (41)$$

where f_o and f_e are the observed and expected frequencies, respectively.

The degrees of freedom in these tests are based on the number of categories and not on the sample size.

One assumption of this test is over the size of the expected frequencies. When the degrees of freedom are 1, the assumption is that all the expected frequencies will be at least 5. When the df is greater than 1, the assumption is that at least 20% of the expected frequencies will be 5.

Yates [5] devised a correction for χ^2 when the degrees of freedom are 1 to allow for the fact that the χ^2 distribution is continuous and yet when $df = 1$, there are so few categories that the χ^2 values from such a test will be far from continuous; hence, the Yates test is referred to as a *correction for continuity*. However, it is considered that this variant on the χ^2 test is only appropriate when the marginal totals are fixed, that is, that they have been chosen in advance [6]. In most uses of χ^2 , this would not be true. If we were looking at gender and smoking status, it would make little sense to set, in advance, how many males and females you were going to sample, as well as how many smokers and nonsmokers.

χ^2 corrected for continuity is found from

$$\chi^2_{(1)} = \sum \frac{(|f_o - f_e| - 0.5)^2}{f_e} \quad (42)$$

where $|f_o - f_e|$ means taking the absolute value, in other words, if the result is negative, treat it as positive.

One-Group Chi-Square/Goodness of Fit

Equal Proportions. In this version of the test, the observed frequencies that occur in each category of a single variable are compared with the expected frequencies, which are such that the same proportion will occur in each category.

Degrees of freedom

The df are based on the number of categories (k); $df = k - 1$.

Example 14 A sample of 45 products are placed into three categories, with 25 in category A, 15 in B, and 5 in C.

The expected frequencies (given the null hypothesis of equal proportions) are calculated by dividing the total sample by the number of categories. Therefore, each category would be expected to have 15 people in it.

$$\begin{aligned} \chi^2 &= 13.33 \\ df &= 2. \end{aligned}$$

The critical value of the χ^2 distribution with $df = 2$ and $\alpha = 0.05$ is 5.99.

Decision: reject H_0 .

Other procedures for rates and proportions are discussed in **Statistical Methods for Counts, Rates, and Proportions**.

Test of Distribution. This test is another use of the previous test, but the example will show how it is possible to test whether a set of data is distributed according to a particular pattern. The distribution could be uniform, as in the previous example, or nonuniform.

Example 15 One hundred scores have been obtained with a mean of 1.67 and a standard deviation of 0.51. In order to test whether the distribution of the scores deviates from being normally distributed, the scores can be converted into z -scores by subtracting the mean from each and dividing the result by the standard deviation. The z -scores can be put into ranges. Given the sample size and the need to maintain at least 80% of the expected frequencies at 5 or more, the width of the ranges can be approximately half a standard deviation except for the two outer ranges, where the expected frequencies get smaller, the further they go from the mean. At the bottom of the range, as the lowest possible

score is 0, the equivalent z -score will be -3.27 . At the top end of the range, there is no limit set on the scale.

By referring to standard tables of probabilities for a normal distribution, we can find out what the expected frequency would be within a given range of z -scores. Table 3 shows the expected and observed frequencies in each range.

$$\chi^2 = 3.56$$

$$df = 8 - 1 = 7.$$

The critical value for a χ^2 distribution with $df = 7$ at $\alpha = 0.05$ is 14.07.

Decision: fail to reject H_0 .

See **Normality Tests** for other tests on normality.

Chi-Square Contingency Test

This version of the χ^2 test investigates the way in which the frequencies in the levels of one variable differ across the other variable. Once again it is for categorical data. An example could be a sample of blind people and a sample of sighted people; both groups are aged over 80 years. Each person is asked whether they go out of their house in a normal day. Therefore, we have the variable visual condition with the levels blind and sighted, and another variable whether the person goes out with the levels yes and no. The null hypothesis of this test would be that the proportions of sighted and blind people going out would be the same (which is the same as saying that the proportions staying in would be the same in each group). This can be rephrased to say that the two variables are independent of each other: the likelihood

of a person going out is not linked to that person's visual condition.

The expected frequencies are based on the marginal probabilities. In this example, that would be the number of blind people, the number of sighted people, the number of the people in the whole sample who go out, and the number of people in the whole sample who do not go out. Thus, if 25% of the entire sample went out, then the expected frequencies would be based on 25% of each group going out and, therefore, 75% of each not going out.

The degrees of freedom for this version of the test are calculated from the number of rows and columns in the contingency table: $df = (r - 1) \times (c - 1)$, where r is the number of rows and c , the number of columns in the table.

Example 16 Two variables A and B each have two levels. Level 1 of variable A has 27 people and 13 are in level 2. Level 1 of variable B has 21 people and 19 are in level 2 (Table 4).

If variables A and B are independent, then the expected frequency for the number who are in the first level of both variables will be based on the fact that 27 out of 40 (or 0.675) were in level 1 of variable A and 21 out of 40 (or 0.525) were in level 1 of variable B . Therefore, the proportion who would be expected to be in level 1 of both variables would be $0.675 \times 0.525 = 0.354375$, and the expected frequency would be $0.354375 \times 40 = 14.175$.

$$\chi^2 = 2.16$$

$$df = (2 - 1) \times (2 - 1) = 1.$$

The critical value of χ^2 with $df = 1$ and $\alpha = 0.05$ is 3.84.

Decision: fail to reject H_0 .

Table 3 The expected (under the assumption of normal distribution) and observed frequencies of a sample of 100 values

From z	To z	f_e	f_o
-3.275	-1.500	6.620	9

	2	15	4	19
	Total	27	13	40

z-Test for Proportions

Comparison between a Sample and a Population Proportion. This test compares the proportion in a sample with that in a population (or that which might be assumed to exist in a population).

The standard error for this test is $\sqrt{\frac{\pi \times (1 - \pi)}{n}}$ where

π is the proportion in the population
 n is the sample size.

The equation for the z -test is

$$\frac{p - \pi}{\sqrt{\frac{\pi \times (1 - \pi)}{n}}} \quad (43)$$

where p is the proportion in the sample.

Example 17 In a sample of 25, the proportion to be tested is 0.7

Under the null hypothesis, the proportion in the population is 0.5

$$z = \frac{0.7 - 0.5}{\sqrt{\frac{0.5 \times (1 - 0.5)}{25}}} = 2.$$

The critical value for z with $\alpha = 0.05$ for a two-tailed test is 1.96.

Decision: reject H_0 .

Comparison of Two Independent Samples. Given two populations, the null hypothesis to be tested is that the proportion having a certain characteristic is equal in both populations. Given a sample from each population, the standard error for this test is

$$\sqrt{\frac{\pi_1 \times (1 - \pi_1)}{n_1} + \frac{\pi_2 \times (1 - \pi_2)}{n_2}} \quad (44)$$

where

π_1 and π_2 are the proportions in each population
 n_1 and n_2 are the sizes of the two samples.

When the population proportions are not known, they are estimated from the sample proportions.

The equation for the z -test is

$$z = \frac{p_1 - p_2}{\sqrt{\frac{p_1 \times (1 - p_1)}{n_1} + \frac{p_2 \times (1 - p_2)}{n_2}}} \quad (45)$$

where p_1 and p_2 are the proportions in the two samples.

Example 18

Sample 1: $n = 30$, $p = 0.7$

Sample 2: $n = 25$, $p = 0.6$

$$z = \frac{0.7 - 0.6}{\sqrt{\frac{0.7 \times (1 - 0.7)}{30} + \frac{0.6 \times (1 - 0.6)}{25}}} = 0.776.$$

Critical value for z at $\alpha = 0.05$ with a two-tailed test is 1.96.

Decision: fail to reject H_0 .

Comparison of Two Correlated Samples. The main use for this test is to judge whether there has been change across two occasions when a measure was taken from a sample. For example, researchers might be interested in whether people's attitudes to a ban on smoking in public places had changed after seeing a video on the dangers of passive smoking compared with attitudes held before seeing the video. A complication with this version of the test is over the estimate of the standard error. A number of versions exist, which produce slightly different results. However, one version will be presented here from Agresti [7]. This will be followed by a simplification, which is found in a commonly used test.

Table 5 shows that originally 40 people were in category A and 44 in category B, and on a second occasion, this had changed to 50 people

Table 5 The frequencies of 84 participants placed in two categories and noted at two different times

		After		
		A	B	Total
Before	A	15	25	40
	B	35	9	44
	Total	50	34	84

being in category A and 34 in category B. This test is only interested in the cells where change has occurred: the 25 who were in A originally but changed to B and the 35 who were in B originally but changed to A. By converting each of these to proportions of the entire sample, $25/84 = 0.297619$ and $35/84 = 0.416667$, we have the two proportions we wish to compare. The standard error for the test is

$$\sqrt{\frac{(p_1 + p_2) - (p_1 - p_2)^2}{n}}$$

where n is the total sample size.

The equation for the z -test is

$$z = \frac{p_1 - p_2}{\sqrt{\frac{(p_1 + p_2) - (p_1 - p_2)^2}{n}}} \quad (46)$$

Example 19 Using the data in Table 5,

$$p_1 = 0.297619$$

$$p_2 = 0.416667$$

$$n = 84$$

$$z = \frac{0.297619 - 0.416667}{\sqrt{\frac{(0.297619 + 0.416667) - (0.297619 - 0.416667)^2}{84}}}$$

$$= -1.304$$

The critical z with $\alpha = 0.05$ for a two-tailed test is -1.96 .

Decision: fail to reject H_0 .

When the z from this version of the test is squared, this produces the Wald test statistic.

A simplified version of the standard error allows another test to be derived from the resulting z -test: McNemar's test of change.

In this version, the equation for the z -test is

$$z = \frac{p_1 - p_2}{\sqrt{\frac{(p_1 + p_2)}{n}}} \quad (47)$$

Example 20 Once again using the same data as that in the previous example,

$$z = -1.291.$$

If this z -value is squared, then the statistic is McNemar's test of change, which is often presented in a further simplified version of the calculations, which produces the same result.

Box and Cox Transformation

The usual assumptions when one analyzes data are the standard assumptions of the linear model (*see Analysis of Variance*), i.e., the additivity of effects, the constancy of variance, the normality of the observations, and the independence of observations. If these assumptions are not met by the data, Tukey [1] suggested two alternatives: either a new analysis must be devised to meet the assumptions, or the data must be transformed to meet the usual assumptions. If a satisfactory transformation is found, it is almost always easier to use than to develop a new method of analysis.

Tukey suggested a family of transformations with an unknown power parameter and Box and Cox [2] modified it to

$$y^{(\lambda)} = \begin{cases} (y^{(\lambda)} - 1)/\lambda & \text{for } \lambda \neq 0 \\ \log y, & \text{for } \lambda = 0 \end{cases} \quad (1)$$

where y is an original observation, $y^{(\lambda)}$ the “new” observation, and λ a real unknown parameter.

Box and Cox assumed that for some λ the n transformed observations

$$\mathbf{y}^{(\lambda)} = \begin{bmatrix} y_1^{(\lambda)} \\ y_2^{(\lambda)} \\ \vdots \\ y_n^{(\lambda)} \end{bmatrix} \quad (2)$$

are independent and normally distributed with constant variance σ^2 and mean vector

$$E\mathbf{y}^{(\lambda)} = A\boldsymbol{\theta} \quad (3)$$

where A is a known $n \times p$ matrix and $\boldsymbol{\theta}$ is a vector of parameters associated with the transformed observations.

Box and Cox [2] estimate the parameters by *maximum likelihood* (*see Maximum Likelihood*) as follows. First, given λ ,

$$\hat{\boldsymbol{\theta}}(\lambda) = (A'A)^{-1}A'\mathbf{y}^{(\lambda)} \quad (4)$$

and

$$\hat{\sigma}^2(\lambda) = \mathbf{y}^{(\lambda)'}[I - A(A'A)^{-1}A']\mathbf{y}^{(\lambda)} \quad (5)$$

are the estimators of $\boldsymbol{\theta}$ and σ^2 , respectively. Second, λ is estimated by maximizing the log likelihood function

$$l(\lambda) = -n \log \hat{\sigma}^2(\lambda)/2 + \log J(\lambda : y) \quad (6)$$

where

$$J(\lambda : y) = \prod_{i=1}^n y_i^{\lambda-1} \quad (7)$$

The maximum-likelihood estimator of λ , say $\hat{\lambda}$, is then substituted into equation (5), which determines the estimators of the other parameters.

Since the original Box–Cox article, there have been many related papers. For example, Draper and Cox [3] derive the precision of the maximum-likelihood estimator of λ for a simple random sample, i.e., $Ey_i^{(\lambda)} = \mu$ for $i = 1, 2, \dots, n$. They found that the approximate variance is

$$V(\hat{\lambda}) = \frac{2}{3n\Delta^2} \left(1 - \frac{1}{3}\gamma_1^2 + \frac{7}{18}\gamma_2 \right)^{-1} \quad (8)$$

where

$$\gamma_1 = \mu_3/\sigma^3 \quad (9)$$

$$\gamma_2 = \mu_4/\sigma^4 - 3 \quad (10)$$

$$\Delta = \lambda\sigma/(1 + \lambda\mu) \quad (11)$$

σ^2 is the variance, and μ_i is the i th central moment of the original observations.

Hinkley [4] generalized the Box–Cox transformation to include power transformations to symmetric distributions and showed his “quick” estimate of λ to be consistent and have a limiting **normal distribution**.

Literature. There are many references related to the Box and Cox transformation. Poirier [5] has extended the Box–Cox work to truncated normal distributions. Some recent results related to large-sample behavior are given by Hernández and Johnson [6]. The Box and Cox [2], Draper and Cox [3], Hinkley [4], and Poirier [5] articles are quite informative but highly technical.

At the textbook level, Chapter 10 of Box and Tiao [7] and Chapter VI of Zellner [8] are excellent introductions to the Box–Cox theory of transformations.

Cumulative Distribution Function (CDF)

The probability that a random variable X does not exceed a value x , regarded as a function of x , is called the *cumulative distribution function of x* . A common notation is

$$F_X(x) = \Pr[X \leq x] \quad (1)$$

See also **Probability Theory**. From the definition, it follows that $0 \leq F_X(x) \leq 1$, and $F_X(x)$ is a nondecreasing function of x .

The notation $F_X(x)$ is intended to indicate that the (mathematical) function of x represents properties of the random variable X . For continuous distributions, the derivative of F_X is the *probability density function* (see **Probability Density Function (PDF)**).

If $F_X(x) \rightarrow 0$ as $x \rightarrow -\infty$ and $F_X(x) \rightarrow 1$ as $x \rightarrow \infty$, the distribution is called *proper*; otherwise, it is called *improper*.

Data Collection

A distinction needs to be made between numbers, adjectives, and other forms of description and data. Numbers and adjectives can be available simply as entities in themselves or as data. The existence of numbers and adjectives does not imply the existence of a set of data, but the existence of a set of data implies the existence of some descriptive forms such as numbers, adjectives, phrases, pictures, graphs, etc. For example, the set of numbers {3, 1, 0, 4, 9, 6} and the set of adjectives {small, pretty, personable, harsh, susceptible, resistant} do not in themselves convey information about any phenomenon. When numbers and adjectives convey information about some entity such as 0, 1, 3, and 4 worms in four particular apples and small, pretty, heat-resistant spores of a bacterium, these facts are denoted as *data*. A *datum* is defined to be a fact (numerical or otherwise) from which a conclusion may be drawn such as, none of the four apples have the same number of worms. A datum contains information whereas a number, adjective, or other form of description may not.

The information in a set of data may be contaminated (mixed up or confounded) with other kinds of information. For example, the particular four apples may have been the only ones in a basket of apples that contained worms and the apples were from a part of the orchard that had a very light infestation of the codling moth. Thus we do not know if 4 out of 120 wormy apples per basket represents the proportion of wormy apples in the entire population of apples or only for this variety in lightly infested orchards. The various factors affecting variation and response are denoted as *sources of variation* in the data.

When the various effects in a set of data are inseparable, they are said to be completely confounded. Partial confounding of effects occurs when the effects are partly mixed together, but it is possible to obtain estimates of each of the various sources of variation. No confounding of effects (orthogonality) implies maximum separability of sources of variation. For example, suppose that there is technician-to-technician variation, day-to-day variation, and method-to-method variation. If technician I conducts method 1 on day 1, technician II method 2 on day 2, technician III method 3 on day 3, etc., one cannot separate the technician effect from the method

effect or from the day effect. If, on the other hand, all technicians used all methods on each of several days, the different effects would be completely separable. The preceding plan would be an orthogonal (completely unconfounded) one, whereas the former would be completely confounded.

Thus the plan or the design of the investigation has a large influence on the confounding aspects in data and hence on the amount of information derivable from the data. With adequate planning and foresight, data can be obtained that have little or no confounding of sources of variation of interest to the investigator. On the other hand, unplanned and/or haphazard collection of data, no matter how voluminous, most frequently results in highly confounded data sets which may be of little or no use in studying effects of various sources of variation. There is a tendency for people to believe that largeness of a data set removes the effects of confounding. This is not necessarily true. The closer one gets to obtaining responses for 100% of the population, the nearer one is to the values of the population parameters (i.e., *see Standard Error* of estimates will be smaller). In this sense, largeness does remove the difficulties of haphazard or selective sampling. However, the complete enumeration of a subpopulation provides no information on the other subpopulation parameters. In this sense, largeness of a set of data does nothing to remove the biases.

Aspects of Data Collection

Whenever data are to be collected, several aspects require consideration. The first one to consider is *why* these data should be collected and what uses these data will serve. If there is no purpose or no use for these data, why collect them? The ready accessibility of computers, together with recording equipment, makes it a simple matter to record voluminous sets of data with relatively little effort. As an illustration, a number of instruments for recording temperature, pulse rate, blood pressure, changes in blood pressure, etc., are attached to a dog undergoing surgery. A minicomputer is used to determine the frequency with which temperature, pulse rate, blood pressure measurements, etc., are recorded. As a second example, suppose that temperature in 100ths of a degree Celsius and humidity in 100ths of a percent are to be recorded every second over a 20-year period in 1000 locations of a field; a

2 Data Collection

minicomputer is used to determine the frequency with which observations are recorded and the observations may be recorded on tape and/or paper. This results in $60 \times 60 \times 24 \times 365.25 \times 1000 \times 20 = 631\,150\,000\,000$ measurements on temperature and the same number on humidity. The data set would consist of more than 1.25 trillion observations. Before embarking on such a large **data collection** venture, one should seriously consider taking fewer measurements (e.g., one every hour rather than 3600 per hour), the uses for data of this nature, and which individuals would actually use these data. Unfortunately, large data sets have been and are being collected, merely on the premise that they might be useful to someone at some time. A computer is available, and data are collected to use the capabilities of the computer.

A second aspect of data collection is *what* data will be collected. All pertinent data for studying a phenomenon should be collected. Thus it is essential to determine what data to collect in light of why the data are collected. Sufficient data should be collected to achieve the goals and purposes of the investigation. Provision should also be made to obtain pertinent data that surface during the course of an investigation. The investigator must be aware of evidence that comes to his or her attention, and obtain the necessary data to explain the phenomenon. An example was given above illustrating how a large data set might be obtained. In some investigations, such as sending missiles to the moon, one can obtain only a few observations on selected entities. In both these cases, it is essential to determine what data to collect.

A third aspect of data collection is *how* and *where* the data are to be collected. The statistician can be very helpful in designing and planning the investigation and in determining how and where the data are to be collected. The how and where of data collection are intimately entwined with the plan and type of the investigation. Also involved are how to measure and quantify information on the various phenomena in an investigation. Measuring methods and gauges must be carefully considered, and it should be ascertained if a measuring instrument is measuring what it is supposed to, and with adequate precision.

Two other aspects to be considered are – *who* is to collect the data and *when* are they to be obtained. Unless these aspects are firmly regulated, the data

may not be collected or only a part of the data may be obtained. In many investigations it is imperative to have unbiased and highly trained technicians to carry out the investigation. The timing of an investigation may be important to its success, and/or it may be necessary to carry out the investigation in a specified time period. If these aspects are ignored, the data may be so unreliable as to make them useless.

In addition to the *why, what, how, where, who, and when* aspects of data collection, it is imperative to have a complete, written description of all data obtained. If this information is recorded only in the investigator's mind, it may soon be lost and be unavailable to other investigators desiring to use the data. Plans need to be made for storage and/or disposal of all data collected. Discarding valuable data that are needed in future research or the storage of useless data result in economic losses that can be avoided with proper planning. Data must be adequately organized and stored on storage devices.

Types of Data Collection

The main types of data collection are historical data, *observational studies* (see **Observational Studies**, including **Internal and External Quality Measures**), and experimental investigations. Historical data (or *happenstance data*, as Box, Hunter, and Hunter call such data sets) are data that have been collected for another purpose, and the investigator has no control over the way in which they are collected. In experiments, the investigator manipulates the system he or she samples data from, thus controlling the sources of variation in the system (varying the factors of interest according to a plan, while keeping other factors as constant as possible). Observational studies are in between in terms of control: the investigator can tailor the data collection design to the purpose he or she has in mind (controlling what data to collect where and when and by whom). The sources of variation are not controlled, however, but the investigator has to work with the values they happen to have.

These different levels of control have their impact on the analysis of the data. The usefulness of historical data is often quite limited. Although the data set can be quite large, unless the observations were guided by an appropriate sampling scheme, there is no reason why they should be representative. Further, strong confounding among sources of variation, or

the omission of factors that have a substantial effect may make it difficult to draw valid conclusions about the research questions. When working with historical data, the investigator must always critically assess whether the data set is usable for his purpose, or that it may be better to discard it.

For observational studies and sample surveys, the investigator draws a sample from the process or population, aiming for this sample to be representative and thus allow an extrapolation of the conclusions to the population (in the case of a *census* one aims for a sample that covers 100% of the population). Some types of sampling methods are

1. Simple random sample

The population does not contain subpopulations and each sampling unit in the population has an equal and independent chance of being selected. An equivalent definition is that every possible sample of size n has an equal chance of being selected.

2. Stratified simple random sample

The population is composed of subpopulations and a simple random sample of sampling units is selected within *each* of the subpopulations (strata).

3. Cluster simple random sample

The population is composed of subpopulations (clusters). A simple random sample of subpopulations (clusters) is made; then a simple random sample is made within each of the selected clusters. When the clusters are areas, the sample survey design is known as an *area-simple random sample*.

4. Every k th sampling unit with a random start

In many cases, a list of sampling units or a serial ordering of sampling units is available. The list is partitioned in subgroups of k items each. A number between 1 and k , say t , is randomly selected. Then the t th item, the $(t + k)$ th item, the $(t + 2k)$ th item, the $(t + 3k)$ th item, etc., form the sample. An example is a sample consisting of products taken from the production line at

9, 9.30, 10, 10.30 a.m., and so on. This survey design is called *systematic* or *cyclic*.

5. More complex designs

There are many types of sample survey designs involving more complexity than the above. Several of the types described above may be included in these designs.

Experimental design is built on the principles laid down by Fisher: **randomization**, **blocking**, and **factorial** designs (*see Assessment of Experimental Designs*). Especially for making inferences about causal relations (*see Causality*), experimental data are generally considered the most powerful. Because of the large extent of control, experimental data are less subject to complications such as confounding.

Degrees of Freedom

The term *degrees of freedom* is used in a number of different fields of science and has a variety of meanings. In statistics, it is most commonly thought of as a parameter (ν) in the χ^2 distribution (denoted χ^2_ν) and in distributions related thereto, such as central and noncentral t and F (see **Probability Density Functions**).

The term *degrees of freedom* for this parameter and the rationale for it go back to R. A. Fisher and his correspondence in 1912 with W. S. Gosset ("Student"). Fisher realized that based on n independent normally distributed sample values $x_1, \dots, x_n$, with sample mean $\bar{x}$, the denominator of the t statistic involves dividing $\sum_{i=1}^n (x_i - \bar{x})^2$ by $(n - 1)$, not by n as Gosset had done and as one would if the true mean μ were known and the sum of squared deviations would be $\sum_{i=1}^n (x_i - \mu)^2$ (see the discussion in [1, pp. 72–73]). In the 1800s Bienaymé and Helmert had proved that $\sum (x_i - \mu)^2 / \sigma^2$ and $\sum (x_i - \bar{x})^2 / \sigma^2$ have χ^2_n and χ^2_{n-1} distributions, respectively, σ^2 being the true variance. However, Fisher took a geometric approach, which is presented in a general way by Stuart and Ord [2, Section 11.2, Exercise 11.6, Section 16.2]; this provides a rationale for applying the term *degrees of freedom* to the parameter of the χ^2 distribution.

Briefly, the joint density of $(x_1, \dots, x_n)$ in Euclidean n space (the sample space of $x_1, \dots, x_n$) when $\mu = 0$ and $\sigma = 1$ is constant over a hypersphere $u = x_1^2 + \dots + x_n^2$ of dimension n , centered at the origin. If one now imposes p functionally independent linear restrictions of the form

$$a_1 x_1 + \dots + a_n x_n = 0 \quad (1)$$

and then restricts the x 's to lie on p hyperplanes through the origin. "The result ... will be to constrain the variables to a hypersphere of p fewer dimensions", i.e., of dimension $n - p$, defining a χ^2_{n-p} distribution. In this context, the term *degrees of freedom* means the dimension of the space in which the relevant hypersphere is constructed.

Degrees of freedom also played a part in the widening rift between Fisher and Karl Pearson [1, pp. 84–87]. Pearson had used χ^2_3 tables to assess the goodness of fit of data in 2×2 contingency tables, but with row and column totals fixed, there

are three linear constraints on four cell frequencies, not one, implying that one should use χ^2 having $(4 - 3 = 1)$ degree of freedom.

In another connotation, the degrees of freedom of a model for expected values of random variables is the excess of the number of variables over the number of parameters in the model. In the case of the *analysis of variance* (see **Analysis of Variance**) or general linear model with independent, homoscedastic **residuals**, the expected value of the **sum of squares** of differences between observed values and corresponding expected values, fitted by *least squares* (see **Least-Squares Estimation**), is

$$\begin{aligned} &(\text{number of degrees of freedom}) \\ &\times (\text{residual variance}) \end{aligned}$$

Further insight into degrees of freedom can be gained from large-sample properties of likelihood-ratio tests. Under certain regularity conditions, suppose that the number of parameters free to vary under a null hypothesis H_0 (possibly composite) and under a more general alternative H_1 are r_0 and r_1 , respectively. Let λ_n be the likelihood ratio, with n being the **sample size**. Then under H_0 [3, Section 13.8] as n increases,

$$-2 \log \lambda_n \rightarrow \chi^2_\nu \quad (2)$$

where $\nu = r_1 - r_0$. Here the degrees of freedom parameter is the difference between the numbers of parameters free to vary under H_1 and H_0 .

Graphical Representation of Data

Graphs, charts, and diagrams offer effective display and enable easy comprehension of complex, multifaceted relationships. Gnanadesikan and Wilk [1] point out that “man is a geometrical animal and seems to need and want pictures for parsimony and to stimulate insight.” Various forms of statistical graphs have been in use for over 200 years.

Beniger and Robyn [2] cite the following as first or near-first uses of statistical graphs: Playfair’s [3] use of the bar chart to display Scotland’s 1781 imports and exports for 17 countries; Fourier’s [4] cumulative distribution of population age in Paris in 1817; Lalanne’s [5] contour plot of temperature by hour and month; and Perozzo’s [6] stereogram display of Sweden’s population for the period 1750–1875 by age groupings. Fienberg [7] notes that Lorenz [8] made the first use of the probability–probability (P–P) plot in 1905. Each of these plots is discussed subsequently. Beniger and Robyn [2], Cox [9], and Fienberg [7] provide additional historical accounts and insights on the evolution of graphics.

Today, graphical methods play an important role in all aspects of a statistical investigation – from the initial exploratory plots, through various stages of analysis, to the final communication and display of results. Many persons consider graphical displays as the single most effective, robust statistical tool.

Not only are graphical procedures helpful but in many cases they are essential. Tukey [10] claims that “the greatest value of a picture is when it forces us to notice what we never expected to see.” This is no better exemplified than by Anscombe’s data sets [11], where plots of four equal-size data sets (Figure 1) reveal large differences among the sets even though all sets produce the same linear regression summaries. Mahon [12] maintains that statisticians’ responsibilities include communication of their findings to decision makers, who frequently are statistically naive, and the best way to accomplish this is through the power of the picture.

Good graphs should be simple, self-explanatory, and not deceiving. Cox [9] offers the following guidelines:

1. The axes should be clearly labeled with the names of the variables and the units of measurement.
2. Scale breaks should be used for false origins.
3. Comparison of related diagrams should be easy, for example, by using identical scales of measurement and placing diagrams side by side.
4. Scales should be arranged so that systematic and approximately linear relations are plotted at roughly 45° to the x axis.
5. Legends should make diagrams as nearly self-explanatory (i.e., independent of the text) as is feasible.
6. Interpretation should not be prejudiced by the technique of presentation.

Most of the graphs discussed here, which involve spatial relationships, are implicitly or explicitly on Cartesian or rectangular coordinate grids, with axes that meet at right angles. The horizontal axis is the *abscissa* or x axis and the vertical axis is the *ordinate* or y axis. Each point on the grid is uniquely specified by an x and a y value, denoted by the ordered pair (x, y) . Ordinary graph paper utilizes linear scales for both axes. Other scales commonly used are logarithmic (see Figure 8) and inverse distribution functions (see Figure 6). Craver [13] includes a discussion of plotting techniques with over 200 graph papers that may be copied without permission of the publisher.

This discussion includes old and new graphical forms that have broad application or are specialized but commonly used. Taxonomies based on the uses of graphs have been addressed by several authors, including Tukey [14], Fienberg [7], and Schmid and Schmid [15]. This discussion includes references to more than 50 different graphical displays (Table 1) and is organized according to the principal functions of graphical techniques:

- Exploration
- Analysis
- Communication and display of results
- Graphical aids

Some graphical displays are used in a variety of ways; however, each display here is discussed only in the context of its widest use.

2 Graphical Representation of Data

Figure 1 Anscombe's [11] plots of four equal-size data sets, all of which yield the same regression summaries [Reprinted with permission from American Statistical Association. ©1973.]

Exploratory Graphs

Exploratory graphs are used to help diagnose characteristics of the data and to suggest appropriate statistical analyses and models. They usually do not require assumptions about the behavior of the data or the system or mechanism that generated the data.

Data Condensation

A listing or tabulation of data can be very difficult to comprehend, even for relatively small data sets. Data condensation techniques, discussed in most elementary statistics texts, include several types of *frequency distributions* (see, e.g., Freund [16] and Johnson and Leone [17]). These distributions associate the frequency of occurrence with each distinct value or distinct group of values in a data set. Ordinarily, data from a continuous variable will first be grouped into intervals, preferably of equal length, which completely cover the range of the data without overlap. The number or length of these intervals is usually best determined from the size of the data set, with larger sets effectively able to support more intervals. Table 2 presents four commonly

used forms: frequency, relative frequency, cumulative frequency, and cumulative relative frequency. Here carbon monoxide emissions (grams per mile) of 794 cars are grouped into intervals of length 24, where the upper limit is included (denoted by the square upper interval bracket) and the lower limit is not (denoted by the lower open parenthesis). Columns 4 and 6 depict relative frequencies, which are scaled versions (divided by 794) of columns 3 and 5, respectively.

The four distributions tabulated in Table 2 are useful data summaries; however, plots of them can help the data analyst develop an even better understanding of the data. A *histogram* is a bar graph associating frequencies or relative frequencies with data intervals. The histogram for carbon monoxide data shown in Figure 2 clearly shows a positively skew (see **Skewness**), unimodal distribution with modal interval (72–96). Other forms of histograms use symbols such as dots (*dot-array diagram*) or asterisks in place of bars, with each symbol representing a designated number of counts.

A *frequency polygon* is similar to a histogram. Points are plotted at coordinates representing interval midpoints and the associated frequency; consecutive

points are connected with straight lines (e.g., in Table 2, plot column 3 *vs* column 2). The form of this graph is analogous to that of a **probability density function**.

A disadvantage of a grouped-data histogram is that individual data points cannot be identified since all the data falling in a given interval are indistinguishable. A display that circumvents this difficulty is the *stem and leaf diagram*, a modified histogram with “stems” corresponding to interval groups and “leaves” corresponding to bars. Tukey [10] gives a thorough discussion of stem and leaf and its variations.

An *ogive* is a graph of the cumulative frequencies (or cumulative relative frequencies) against the upper limits of the intervals (e.g., from Table 2, plot column 5 *vs* the upper limit of each interval in column 1) where straight lines connect consecutive points. An ogive is a grouped-data analog of a graph of the empirical cumulative distribution function and is especially useful in graphically estimating percentiles (see **Quantiles**), which are data values associated with specified cumulative percents. Figure 3 shows the ogive for the carbon monoxide data and how it is used to obtain the 25th percentile (i.e., the lower quartile).

^(a) Notation designates inclusion of all values greater than 24 and less than or equal to 48

Another display, which highlights five important characteristics of a data set, is a *box and whisker* or box plot. The box, usually aligned vertically, encloses the interquartile range (see **Descriptive Statistics**), with the lower line identifying the 25th percentile (lower *quartile*, see **Quartiles**) and the upper one the 75th (upper quartile). A line sectioning the box displays the 50th percentile (median) and its relative position within the interquartile range. The whiskers at either end may extend to the extreme values, or, for large data sets, to the 10th/90th

or 5th/95th percentiles. These plots are especially convenient for comparing two or more data sets, as shown in Figure 4 for winter snowfalls of Buffalo and Rochester, New York. (See Tukey [10] for further discussion, and McGill *et al.* [18] for some variations.)

Relationships between Two Variables

Often of interest is the relationship, if any, between x and y , or the development of a model to predict y

Figure 3 Ogive of automobile carbon monoxide emissions data shown in Figure 2

Figure 4 Box and whisker plots comparing winter snowfalls of Buffalo and Rochester, New York, (1939–1940 to 1977–1978) and demonstrating little distributional difference (contrary to popular belief). (Based on local climatological data gathered by the National Oceanic and Atmospheric Administration, National Climatic Center, Asheville, NC)

given the value of x . Ordinarily, an (x, y) measurement pair is obtained from the same experimental unit, as shown in Table 3.

A usual first step is to construct a *scatter plot*, a collection of plotted points representing the measurement pairs (x_i, y_i) , $i = 1, \dots, n$. The importance of scatter plots was seen in Figure 1. These four very different sets of data yield the same regression line

Table 3

Unit	x	y
Object	Diameter	Weight
Person	Age	Height
Product	Raw material purity	Quality

(drawn on the plots) and associated statistics [11]. Consequently, the numerical results of an analysis, without the benefit of a look at plots of the data, could result in invalid conclusions.

The objective of regression analyses is to develop a mathematical relationship between a measured response or dependent variable, y , and two or more predictor or independent variables, $x_1, x_2, \dots, x_p$. A usual initial step is to plot y versus each of the x variables individually and to plot each x_i versus each of the other x 's. This results in a total of $p + p(p - 1)/2$ plots. Plots of y versus x_i enable one to identify the x_i variables that appear to have large effects, to assess the form of a relationship between the y and x_i variables, and to determine whether any unusual data points are present. Plots of x_i versus x_j , $i \neq j$, help to identify strong correlations that may exist among the predictor variables. It is important to recognize such correlations because least-squares regression techniques work best when these correlations are small [19] (see **Collinearity; Data Collection**).

In many instances data are collected sequentially in time and a plot of the data versus the sequence of collection can help identify sources of important effects. Figure 5 shows a *sequence plot* of gasoline mileage of an automobile versus the sequence of gasoline fill-ups. The large seasonal effect (summer mileage is higher than winter mileage) and the increase in gasoline mileage due to a major tune-up are clearly evident.

Observations collected sequentially in time, such as the gasoline mileage data plotted in Figure 5, form a time series (see **Time Series Analysis**). Statistical modeling of a time series is largely accomplished by studying the correlation between observations separated by $1, 2, \dots, n - 1$ units in time. For example, the lag-1 autocorrelation is the correlation coefficient between observations collected at time i and time $i + 1$, $i = 1, 2, \dots, n - 1$; it measures the linear relationship among all pairs of consecutive observations (see **Autocorrelation Function**). An *autocorrelation*

Figure 5 Sequence plot of gasoline mileage data. Note the seasonal variation and the increased average value and decreased variation in mileage after tune-up

plot may be used to study the “correlation structure” in the data where the lag- j autocorrelation coefficient computed between observations i and $i + j$ is plotted *versus* lag j . A *cross-correlation plot* between two time series is developed similarly. The lag- j correlation coefficient, computed between observations i in one series and observations $i + j$ in the other series, is plotted *versus* the lag j . Box and Jenkins [20] discuss the construction and interpretation of these plots, in addition to presenting examples on the use of sequence plots and the modeling of time series.

Relationships among More than Two Variables

Scatter plots directly display relationships between two variables. Values of a third variable can be incorporated in a *labeled scatter plot*, in which each plotted point (whose location designates the values of two variables) is labeled by a symbol designating a level of the third variable. Anderson [21] extended these to “pictorialized” scatter plots, called *glyphs* and *metroglyphs*, where each coordinate point is plotted as a circle and has two or more rays emanating from it; the length of each ray is indicative of the value of the variable associated with that ray. Bruntz *et al.* [22] developed a variation of the glyph for four variables, called the *weathervane plot*, where values of two of the variables are again indicated by the plotted coordinates and the other two by using

variable-sized plotting symbols and variable-length arrows attached to the symbols.

Tukey [10], Gabriel’s *biplot* [23], and Mandel [24] provide innovative methods for displaying two-way tables of data. All three approaches involve fitting a model to the table of data and then constructing various plots of the coefficients in the fitted model to study the relationships among the variables.

Chernoff [25] used facial characteristics to display values of up to 18 variables through *face plots*. Each face represents a multivariate datum point, and each variable is represented by a different facial characteristic, such as size of eyes or shape of mouth. Experience has shown that the interpretation of these plots can be affected by how the variables are assigned to facial characteristics.

Exploratory plots of raw data are usually less effective with measurements on four or more variables (e.g., height, weight, age, sex, race, etc., of a subject). The usual approach then is to reduce the dimensionality of the data by grouping variables with common properties or identifying and eliminating unimportant variables. The variables plotted may be functions of the original variables as specified by a statistical model. Exploratory analysis of the data is then conducted with plots of the “reduced” data. Andrews’ *Fourier plots* [26], *data clustering* [27], *similarity and preference mapping* [28], and geometrical representations of multidimensional scaling

analyses [29] are examples of such procedures. One often attempts to determine whether there are two or more groups (i.e., clusters) of observations within the data set. When several different groups are identified, the next step is usually to determine why the groups are different. These methods are sophisticated and require computer programs for implementation on a routine basis. (See Gnanadesikan [30], Everitt [31].)

Graphs Used in the Analysis of Data

The graphical methods discussed next generally depend on assumptions of the analysis. Decisions made from these displays may be either subjective in nature, such as a visual assessment of an underlying distribution, or objective, such as an out-of-control signal from a control chart.

Distribution Assessment and Probability Plots

The *probability plot* is a widely used graphical procedure for data analysis. Since other graphical techniques discussed in this article require a basic understanding of it, a brief discussion follows (see **Probability Plots**).

A probability plot on linear rectangular coordinates is a collection of two-dimensional points specifying corresponding quantiles from two distributions. Typically, one distribution is empirical and the other is a hypothesized theoretical one. The primary purpose is to determine visually if the data could have arisen from the given theoretical distribution. If the empirical distribution is similar to the theoretical one, the expected shape of the plot is approximately a straight line; conversely, large departures from linearity suggest different distributions and may indicate how the distributions differ.

Imagine a sample of size n in which the data $y_1, \dots, y_n$ are independent observations on a random variable Y having some continuous distribution function (df) (see **Probability Density Function (PDF)**). The ordered data $y_{(i)}, y_{(1)} \leq \dots \leq y_{(n)}, i = 1, \dots, n$, represent sample **Quantiles** and are plotted against theoretical quantiles, $x_i = F^{-1}(p_i)$, where F^{-1} denotes the inverse of F , the hypothesized df of Y . Moreover, $F(y)$ may involve unknown location (v) and scale (δ) parameters (not necessarily the mean and the standard deviation) as long as $F((y - v)/\delta)$ is completely specified. If Y has a df F ,

then $p_i = F(x_i) = F((y_{(i)} - v)/\delta)$; x_i is called the *reduced $y_{(i)}$ variate* and is a function of the unknown parameters.

Selection of p_i for use in plotting has been much discussed. Suggested choices have been $i/(n+1)$, $(i-1/2)/n$, $(2i-1)/2n$, and $(i-3/8)/(n+1/4)$. Kimball [32] discusses some choices of p_i in the context of probability plots.

Now $F^{-1}(p_i)$ is not expressible in closed form for most commonly encountered distributions and thus provides an obstacle to easy evaluations of x_i . An equivalent procedure often employed to avoid this difficulty is to plot $y_{(i)}$ against p_i on *probability paper*, which is rectangular graph paper with an F^{-1} scale for the p axis. The p_i entries on the p axis are commonly called *plotting positions*. Naturally, a different type of probability paper is needed for each family of distributions, F .

Normal probability paper, with F^{-1} based on the normal distribution, is most common, although many others have been developed (see, e.g., King [33]). Normal probability paper is available in two versions: arithmetic probability paper, where the data axis has a linear scale, and logarithmic probability paper, where the data axis has a natural logarithmic scale. The latter version is used to check for a lognormal distribution (see **Probability Density Functions**).

To illustrate the procedure, two data sets of size $n = 15$ have been plotted on normal (arithmetic) probability paper shown in Figure 6, using $p_i =$

Figure 6 Comparison of two data sets plotted on normal probability paper. Set I can be adequately approximated by a **normal distribution**, whereas set II cannot

8 Graphical Representation of Data

$i/(n+1)$. Here the horizontal axis is labeled in percentage; $100p_i$ has been plotted against the i th smallest observation in each set. The plotted points of set I appear to cluster around the straight line drawn through them, visually supportive evidence that these data come from a population that can be adequately approximated by a normal distribution. The points for set II, however, bend upward at the higher percents, suggesting that the data come from a distribution with a longer upper tail (i.e., larger upper quantiles) than the normal distribution.

If set I data are viewed as sufficiently normal, graphical estimates of the mean (μ) and the standard deviation (σ) are easily obtained by noting that the 50th percentile of the normal distribution corresponds to the mean and that the difference between the 84th and 50th percentiles corresponds to one standard deviation. The respective graphical estimates from the line fitted by eye for μ and σ are 5.7 and $7.0 - 5.7 = 1.3$, respectively.

The conclusions from Figure 6 were expected because the data from set I are, in fact, random normal deviates with $\mu = 6$ and $\sigma = 1$. The data in set II are random lognormal deviates with $\mu = 0.6$ and $\sigma = 1$. A plot of set II data on logarithmic probability paper produces a more nearly linear collection of points.

Visual inference, such as determining here whether the collection of points forms a straight line, is fairly easy, but should be used with theoretical understanding to enhance its reliability. A curvilinear pattern of points based on a large sample offers more evidence against the hypothesized distribution than does the same pattern based on a smaller sample. For example, the plot of set I data exhibits some asymmetric irregularities, which are due to random fluctuations; however, a similar pattern of irregularity based on a much larger sample would be much more unlikely from a normal distribution. Daniel [34] and Daniel and Wood [35] give excellent discussions on the behavior of normal probability plots.

The probability plot is a special case of the quantile–quantile ($Q-Q$) plot [36] (see **Probability Plots**), which is a quantile–quantile comparison of two distributions, either or both of which may be empirical or theoretical; whereas a probability plot is typically a display of sample data on probability paper (i.e., empirical vs theoretical). $Q-Q$ plots are particularly useful because a straight line will result when comparing the distributions of X and

Y , whenever one variable can be expressed as a linear function of the other. $Q-Q$ plots are relatively more discriminating in low-density or low-frequency regions (usually the tails) of a distribution than near high-density regions, since in low-density regions quantiles are rapidly changing functions of p . In the plot, this translates into comparatively larger distances between consecutive quantiles in low-density areas. The quantiles in Figure 6 illustrate this, especially the larger empirical ones of set II.

A related plot considered by Wilk and Gnanadesikan [36] is the $P-P$ plot. Here, for varying x_i , $p_{i1} = F_1(x_i)$ is plotted against $p_{i2} = F_2(x_i)$, where F_j , $j = 1, 2$, denotes the df (empirical or theoretical). If $F_1 = F_2$ for all x_i , the resulting plot is a straight line with unit slope through the origin. This plot is especially discriminating near high-density regions, since here the probabilities are more rapidly changing functions of x_i than in low-density regions. The $P-P$ plot is not as widely used as the $Q-Q$ plot since it does not remain linear if either variable is transformed linearly (e.g., by a location or scale change).

For large data sets, an obvious approach for comparison of data with a probability model is a graph of a fitted theoretical density (parameters estimated from data), with the appropriate scale adjustment, superimposed on a histogram. Gross differences between the ordinates of the distributions are easily detected. A translation of the differences to a reference line (instead of a reference curve) to facilitate visual discrimination is easily accomplished by hanging the bars of the histogram from the density curve [37].

Figure 7 Hanging carbon monoxide histogram from fitted lognormal distribution

Figure 7 illustrates the *hanging histogram*, where the histogram for the carbon monoxide data (Figure 2) is hung from a lognormal distribution. Slight, systematic variation about the reference line suggests that the data are slightly more skewed to the right in the high-density area than in the lognormal distribution.

Further improvements in detecting systematic variation may be achieved by rootograms [37]. A *hanging rootogram* is analogous to a hanging histogram except that the square roots of the ordinate values are graphed. The *suspended rootogram* is an upside-down graph of the **residuals** about the baseline of the hanging rootogram.

Graphical assessments for discrete distributions can also be made by comparing the histogram of the data to the fitted probability density, $p(x)$. However, as with continuous distributions, curvilinear discrimination may be difficult and linearizing procedures are helpful. A general approach is to determine a function of $p(x)$, say, $r(x) = r(p(x))$, which is linearly related to a function of x , say, $s(x)$. Then using sample data one calculates relative frequencies to estimate $p(x)$, evaluates $r(x)$, and plots $r(x)$ against $s(x)$. The absence of systematic departures from linearity offers some evidence that the data could arise from density $p(x)$. The slope and intercept will be functions of the parameters and can be used to estimate the parameters graphically. A suitable $r(x)$ may be obtained by simply transforming $p(x)$; for example, taking logarithms of the density of the discrete **Pareto** distribution, where $p(x) \propto x^\lambda$, gives $r(x) = \log p(x)$ and $s(x) = \log x$. In other cases, ratios of consecutive probabilities (e.g., $p(x+1)/p(x)$) are linear functions of $s(x)$ [38]. Table 4 summarizes these ratios for three commonly encountered discrete distributions.

Ord [39] expands on the foregoing ideas by defining a class of discrete distributions where $r(x) = xp(x)/(p(x-1))$ is a linear function of x (i.e., $s(x) = x$), thereby keeping the same abscissa scale. Distributions in this class are binomial, negative binomial, Poisson, logarithmic, and uniform.

These graphical tests for discrete distributions may be difficult to interpret because the sample relative frequencies have nonhomogeneous variances. This difficulty may be compounded when using ratios of the relative frequencies as functions of $s(x)$. These procedures are therefore recommended more as exploratory than confirmatory.

Another graphical technique for the Poisson distribution (see **Probability Density Functions**) is the *Poissonness plot* [40], similar in spirit to probability plotting. It can also be applied to truncated Poisson data or any one-parameter exponential family of discrete distributions such as the binomial.

For further insights, see Parzen [41].

Model Adequacy and Assumption Verification

Any statistical analysis is based on certain assumptions. Those usually associated with least-squares regression analysis are that experimental errors are independent and have a homogeneous variance and a normal (Gaussian) distribution. It is standard practice to check these assumptions as part of the analysis. These checks, most often done graphically, have the desirable by-product of forcing the analyst to look at the data critically. This can be effectively accomplished by graphical analysis of both the raw data and residuals from the fitted model. In addition to assumption verification, this evaluation frequently results in the discovery of unusual observations or unsuspected relationships. Most of the plots discussed below are applications of graphical forms previously discussed.

If repeat observations have been obtained for each of k groups representing different situations or conditions being studied, a scatter plot of the group standard deviation, s_i , versus the group mean, $\bar{y}_i$, $i = 1, \dots, k$, will appear random and show little correlation when the homogeneous variance assumption is satisfied. Box *et al.* [42] point out that if these assumptions are not satisfied, this plot can be used to determine a transformed measurement scale on which the assumptions will be more nearly satisfied (Figure 8).

The normal distribution assumption can be checked in this situation from a histogram of the **Residuals**, $r_{ij} = y_{ij} - \bar{y}_i$, between the observations in each group (y_{ij}) and the average of the group ($\bar{y}_i$). This histogram will tend to be bell-shaped if the normal distribution and homogeneous variance assumptions are satisfied. Alternatively, especially for small data sets, the r_{ij} 's may be plotted on normal probability paper. The expected shape is a straight line if these assumptions are appropriate.

Replicate observations often are not available. However, the analysis assumptions and adequacy of the form of the model can still be checked by

Table 4

Distribution	$p(x)$	$r(x)$	=	Intercept	+	Slope	$\times$	$s(x)$
Binomial	$\binom{n}{x}\pi^x(1-\pi)^{n-x}, x = 0, \dots, n$	$\frac{p(x+1)}{p(x)}$		$-\frac{\pi}{1-\pi}$		$\frac{(n+1)\pi}{1-\pi}$		$\frac{1}{x+1}$
Poisson	$\frac{e^{-\lambda}\lambda^x}{x!}, x = 0, 1, 2, \dots$	$\frac{p(x)}{p(x+1)}$		$\frac{1}{\lambda}$		$\frac{1}{\lambda}$		x
Pascal	$\binom{x-1}{k-1}\pi^k(1-\pi)^{x-k}, x = k, k+1, \dots$	$\frac{p(x)}{p(x+1)}$		$\frac{1}{1-\pi}$		$\frac{k-1}{1-\pi}$		$\frac{1}{x}$

Figure 8 Toxic agent data [42, Table 7.11]. Linear log–log relationship suggests that a power transformation will produce homogeneous variances. The slope of the line indicates the necessary power [©WileyInterscience.]

constructing plots of the residuals or standardized residuals [43], from the fitted model. The residual associated with observation y_i is $r_i = y_i - \hat{y}_i$, where $\hat{y}_i$ is the value of y_i predicted by the model fitted to the data. Four types of *residual plots* are routinely constructed [44]: plots on normal probability paper, residuals (r_i) versus predicted values ($\hat{y}_i$), sequence plot of residuals, and residuals (r_i) versus predictor variables (x_j). Note that although the residuals are not mutually independent, the effect of

the correlation structure on the utility of these plots is negligible [45].

The *plot of residuals on normal probability paper* provides a check on the normal distribution assumption. Substantive deviations from linearity may be due to a nonnormal distribution of experimental errors, the presence of atypical (i.e., outlying) data points, or an inadequate model (Figure 9).

The *residuals (r_i) versus the predicted values ($\hat{y}_i$) plot* will show a random distribution of points (no trends, shifts, or peculiar points) if all assumptions are satisfied. Any curvilinear relationship indicates that the model is inadequate (Figure 10). Nonhomogeneous variance is indicated if the spread in r_i changes with $\hat{y}_i$. When the spread increases linearly with $\hat{y}_i$, a log transformation (i.e., replace y in the analysis

Figure 9 Normal probability plot of residuals. Plot (a) shows an outlying data point and plot (b) shows a set of residuals not normally distributed

Figure 10 Residuals *versus* fitted values. Plot (a) shows increased residual variability with increasing fitted values and plot (b) shows a curvilinear relationship

by $y' = \log y$) will often produce a response scale on which the homogeneous variance assumption will be satisfied (Figure 10). Plots of the residuals (r_i) *versus* raw observations (y_i) are of little value because they will always show a linear correlation with a value of $(1 - R^2)^{1/2}$, where R^2 is the coefficient of determination (see **Coefficient of Determination (R^2)**) of the fitted model [46].

If all analysis assumptions are satisfied, the *sequence plot of the residuals* (r_i) can be expected to show a random distribution of points and contain no trends, shifts, or atypical points. Any trends or shifts here suggest that one or more variables not included in the model may have changed during the collection of the data (Figure 11). This plot may show cycles in the residuals and other dependencies, indicating that the assumption of independence of experimental errors is not appropriate. This assumption can also be checked by constructing an *autocorrelation plot* of the residuals (see earlier discussion).

The *residuals* (r_i) *versus* the *predictor variables* (x_i) *plot* should also show a random distribution of points. Any smooth patterns or trends

Figure 11 Sequence plot of residuals. Plot (a) shows an abrupt change and plot (b) shows a gradual change due to factors not accounted for by the model

suggests that the form of the model may not be appropriate (Figure 12).

The scatter plots of residuals discussed above are not independent of each other. Peculiarities and trends observed in one plot usually show up in one or more of the others. Collectively, these plots provide a good check on data behavior and the model construction process.

With a large number of predictor variables it is sometimes hard to see relationships between y and x_i in scatter plots. Larsen and McCleary [47] developed the *partial residual plot* to overcome this problem. Wood [48] and Daniel and Wood [35] refer to these as *component-plus-residual plots*. A regression model must be fitted to the data before the plot can be constructed. In effect, the relationships of all the other variables are removed and the plot of the component-plus-residual *versus* x_i displays only the computed relationship between y and x_i and the residual variation in the data.

Figure 12 Residuals *versus* a predictor variable

Plots for Decision Making

At various points in a statistical analysis, decisions concerning the effects of variables and differences among groups of data are made. Statisticians and other scientists have developed a variety of statistical techniques that use graphical displays to make these decisions. In some instances (e.g., control charts, Youden plots) these contain both the data in raw or reduced form and a measure of their uncertainty. The user, in effect, makes decisions from the plot rather than by calculating a test statistic. In other situations (e.g., half-normal plot, ridge trace) a measure of uncertainty is not available but the analyst makes decisions concerning the magnitude of an effect or the appropriateness of a model by assessing deviations from expected or desired appearance.

The *control chart* (see **Control Charts, Overview**) is widely used to control industrial production and analytical measurement processes [49]. It is a *sequence plot* of a measurement or statistic (average, range, etc.) *versus* time sequence together with limits to reflect the expected random variation in the plotted points. For example, on a plot of sample averages, limits of ± 3 standard deviations are typically shown about the process average to reflect the uncertainty in the averages. The process is considered to be out of control if a plotted average falls outside the limits. This suggests that a process shift has occurred and a search for an **assignable cause** should be made. The *cumulative sum control chart* (see **Cumulative Sum (CUSUM) Chart**) is another popular **process control** technique, particularly useful in detecting small process shifts [50, 51].

Ott [53] used the control chart concept to develop his analysis-of-means plotting procedure for the interpretation of data that would ordinarily be analyzed by analysis-of-variance techniques. Schilling [54, 55] systematized Ott's procedure and extended it past the cross-classification designs to **incomplete block** experiments and studies involving random effects. The analysis-of-means procedure enables those familiar with control chart concepts and technology to quickly develop an ability to analyze the results from experimental designs.

The *Youden plot* [56] was developed to study the ability of laboratories to perform a test procedure. Samples of similar materials, A and B, are sent to a number of laboratories participating in a collaborative test. Each laboratory runs a predetermined number of replicate tests on each sample for a number of different characteristics. A Youden plot is constructed for each measured characteristic. Each point represents a different laboratory, where the average of the replicate results on material A is plotted *versus* the average results on material B (Figure 13). Differences along a 45° line reflect between-lab variation. Differences in the direction perpendicular to the 45° line reflect within-lab and lab-by-material interaction variation. An uncertainty ellipse can be used to identify problem laboratories. Any point outside this ellipse is an indication that the associated laboratory's results are significantly different from those of the laboratories within the ellipse. Mandel and Lashof [52] generalized and extended

Figure 13 Youden plot [52] [©American Society of Quality, 1974.]

the construction and interpretation of Youden's plot. Ott [57] showed how this concept can be used to study paired measurements. For example, "before" and "after" measurements are frequently collected to evaluate a process change or a manufacturing stage of an industrial process.

Daniel [34] developed the **Half-Normal Plot** to interpret two-level factorial and fractional **Factorial Experiments**. It displays the absolute value of the $n - 1$ contrasts (i.e., main effects and interactions) from an n -run experiment, *versus* the probability scale of the half-normal distribution (Figure 14). Identification of large effects (positive or negative) is enhanced by plotting the absolute value of the contrast. Alternatively, to preserve the sign of the contrast, the contrast value may be plotted on normal probability paper [42]. With no significant effects, either plot will appear as a straight line. Significant effects are indicated by the associated contrast falling off the line. Although this plot is usually assessed visually, uncertainty limits and decision guides have been developed by Zahn [58, 59]. The half-normal plot is not restricted to two-level experiments and can be used in the interpretation of any experiment for which the effects can be described by independent 1-degree-of-freedom contrasts.

The half-normal plot was significant in marking the beginning of extensive research on probability plotting methods in the early 1960s. During this time the statistical community became convinced of the usefulness and effectiveness of graphical techniques; many of these developments were discussed earlier.

Figure 14 Half-normal plot from a 2^{5-1} factorial experiment showing four important effects on a color response

Figure 15 C_p plot [60]. The six variables in the equation are denoted by a , b , c , d , e , and f . The number of terms in the equation is denoted by P [Reprinted with permission from American Statistical Association. ©1966.]

Research in the 1960s and 1970s also focused on regression analysis and the fitting of equations to data when the predictor variables (x 's) are correlated. Two displays, the C_p plot and the *ridge trace*, were developed as graphical aids in these studies.

The C_p plot, suggested by C. L. Mallows and popularized by Gorman and Toman [60] and Daniel and Wood [35], is used to determine which variables should be included in the regression equation. It (Figure 15) is constructed by plotting, for each equation considered, C_p versus p , where $C_p = \text{RSS}_p / s^2 - (n - 2p)$, p is the number of terms in the equation, RSS_p is the residual **sum of squares** for the p -term equation of interest, n is the total number of observations, and s^2 is the residual mean square obtained when all the variables are included in the equation. If all the important terms are in the equation, $C_p = p$. The line $C_p = p$ is included on the plot and one looks for the equations that have points falling near this line. Points above the line indicate that significant terms have not been included. The objective is to find the equation with the smallest

number of terms for which $C_p \doteq p$.

The *ridge trace*, developed by Hoerl and Kennard [19] and discussed by Marquardt and Snee [61], identifies which regression coefficients are poorly estimated because of correlations among the predictor variables (x 's). This is accomplished by plotting the regression coefficients *versus* the **bias** parameter, k , which is used to calculate the ridge regression coefficients, $\hat{\beta} = (\mathbf{X}'\mathbf{X} + k\mathbf{I})^{-1}\mathbf{X}'\mathbf{Y}$ (Figure 16). Coefficients whose sign and magnitude are affected by correlations among the predictor variables (x 's) will change rapidly as k increases. Hoerl and Kennard recommend that an appropriate value for k is the smallest for which the coefficients “stabilize” or change very little as k increases. If the coefficients remain nearly constant for $k > 0$, then $k = 0$ is suggested; this indicates that the least-squares coefficients should be used.

Communication and Display of Results

Quantitative Graphics

Quantitative graphics encompass general methods of presenting and summarizing numerical information,

Figure 16 Ridge trace showing instability of regression coefficients 1 and 2

usually for easy comprehension by the layman. There can be no complete catalog of these graphics since their form is limited only by one's ingenuity. Beniger and Robyn [2] trace the historical development since the seventeenth century of quantitative graphics and offer several pictorial examples illustrating the improved sophistication of graphs. Schmid and Schmid [15], in a comprehensive handbook, discuss and illustrate many quantitative graphical forms. A few of the more common forms follow briefly.

A *bar chart* is similar in appearance to a histogram (Figure 2) but more general in application. It is frequently used to make quantitative comparisons of qualitative variables, as a company might do to compare revenues among departments. Comparisons within and between companies are easily made by superimposing a similar graph of another comparable company and identifying the bars.

A *pictogram* is similar to the bar chart except that “bars” consist of objects related to the response tallied. For example, figures of people might be used in a population comparison where each figure represents a specified number of people [62]. When partial objects are used (e.g., the bottom half of a person), it should be stated whether the height or volume of the figure is proportional to frequency.

A *pie chart* is a useful display for comparing attributes on a relative basis, usually a percentage. The angle formed by each slice of the pie is an indication of that attribute's relative worth. Governments use this device to illustrate the number of pennies of a taxpayer's dollar going into each major budget category.

A *contour plot* may effectively depict a relationship among three variables by one or more contours. Each contour is a locus of values of two variables associated with a constant value of the third. A relief map that shows latitudinal and longitudinal locations of constant altitude by contours or isolines is a familiar example. Contours displaying a **response surface**, $y = f(x_1, x_2)$, are discussed subsequently (Figure 21). A *stereogram* is another form for displaying spatial relationship of three variables in two dimensions, similar to a draftsman's three-dimensional perspective drawing in which the viewing angle is not perpendicular to any of the object's surfaces (planes).

The field of *computer graphics* has rapidly expanded, offering many new types of graphics, see Tufte [63].

Summary of Statistical Analysis

Many of the displays previously discussed are useful in summarizing and communicating the results of a study. For example, histograms or dot-array diagrams are used to display the distribution of data. Box plots are useful (see Figure 4) for large data sets or when several groups of data are compared.

The results of many analyses may be displayed by a *means plot* of the group means ($\bar{y}$) together with a measure of their uncertainty, such as **standard error** ($\bar{y} \pm \text{SE}$), confidence limits ($\bar{y} \pm t\text{SE}$), or least significant interval limits ($LSI = \bar{y} \pm \text{LSD}/2$). The use of the LSI [65] is particularly advantageous because the intervals provide a useful decision tool (Figure 17). Any two averages are significantly different at the assigned probability level if and only if their LSIs do not overlap. Intervals based on the standard error and confidence limits for the mean do not have this straightforward interpretation. Similar intervals can be developed for other multiple comparison procedures, such as those developed by Tukey (honest significant difference), Dunnett, or Scheffé.

Box *et al.* [42] use the *sliding reference distribution* to display and compare means graphically. The distribution width is determined by the **Standard Error** of the means. Any two means not within the bounds of the distribution are judged to

be significantly different. They also use this display in the interpretation of factor effects in two-level factorial experiments.

The *notched-box plot* of McGill *et al.* [18] is the nonparametric analog of the LSI-type plots discussed above. The median of the sample and confidence limits for the difference between two medians are displayed in this plot; any two medians whose intervals do not overlap are significantly different. McGill *et al.* [18] discuss other variations and applications of the box plot.

Factorial experimental designs (see **Factorial Experiments**) are widely used in science and engineering. In many instances the effects of two and three variables are displayed on *factor space/response plots* with squares and cubes similar to those shown in Figure 18. The numbers in these figures are the mean responses obtained at designated values of the independent variables studied. These figures show the region, or factor space, over which the experiments were conducted, and aid the investigator in determining how the response changes as one moves around in the experimental region.

An *interaction plot* is used to study the nature and magnitude of the interaction of two variables from a designed experiment by plotting the response (averaged over all replicates) *versus* the level of one of the independent variables while holding the

Figure 17 Least significant interval plot [64] [©International Biometrics Society, 1979.]

Figure 18 Factor space/response plots showing results of 2^2 and 2^3 experiments. The average responses are shown at the corners of the figures [66]

other independent variable(s) fixed at a given level. In Figure 19 it is seen by the nonparallel lines that the size of the effect of solution temperature on weight loss depends on whether stirring occurred. Solution temperature and stirring are said to *interact*; another way of saying that their effects are not additive. Monlezun [67] discusses ways of plotting and interpreting three-factor interactions.

The objective of many experiments is to develop a prediction model for the response (y) of the system as a function of experimental (predictor) variables. A typical two-predictor variable model, based on a second-order Taylor series, is

$$y = b_0 + b_1X_1 + b_2X_2 + b_{12}X_1X_2 + b_{11}X_1^2 + b_{22}X_2^2 \quad (1)$$

where the b 's are coefficients estimated by regression analysis techniques. One of the best ways to understand all the effects described by this equation is by a *contour plot*, which gives the loci of X_1 and X_2 values associated with a fixed value of the response. By constructing contours on a rectangular $X_1 - X_2$ grid for a series of fixed values of y , one obtains a global picture of the response surface (Figure 20a).

Figure 19 Nonparallelism of lines suggests an interaction between stirring and solution temperature. Stirring has a larger effect at 30 °C than at 0 °C

Figure 20 Contour plot of (a) quadratic response surface and (b) X_1 – X_2 interaction plot [70] [©American Association for Clinical Chemistry, 1979.]

Figure 21 Joint 95% β_1 – β_2 confidence regions for coal classes A, B, C, and D [74] [©American Society for Quality, 1973.]

The response surface of a mixture system such as a gasoline or paint can be displayed by a contour plot on a triangular grid [68, 69]. Another use of trilinear coordinates is shown in Figure 22.

Predicted response plots help in interpreting interaction terms in regression equations [71]. The interaction between X_i and X_j is studied by fixing the other variables in the equation at some level (e.g., set $X_k = \bar{X}_k, k \neq i, j$) and constructing an interaction plot of the values predicted by the equation for different values of X_i and X_j (Figure 20b). Similar plots are also useful in interpreting response surface models for mixture systems [72] and in the analysis of the results of mixture screening experiments [73].

A contour plot is also the basis for a *confidence region plot*, used to display a plausible region of simultaneous hypothesized values of two or more parameters. For example, Figure 21 [74] shows a contour representing the joint confidence region (see **Confidence Intervals**) for regression parameters β_1 and β_2 associated with each of four coal classes. The figure clearly shows that these four groups do not all have the same values of regression parameters.

Confidence region plots on trilinear coordinates [75] can also be used to display and identify variable dependence in two-way contingency tables where one variable is partitioned into three categories (see also Draper *et al.* [76]). A two-dimensional plot results (Figure 22) from the constraint that the sum of the

Figure 22 Joint 95% confidence region plots for hair color probabilities for brown, hazel, green, and blue eye colors [75] [Reprinted with permission from American Statistical Association. ©1974.]

three probabilities, π_1, π_2 , and π_3 , is unity. It is also possible to display three-dimensional response surfaces or confidence regions *via* a series of two-dimensional slices through three-dimensional space.

Graphical Aids

Statisticians, like chemists, physicists, and other scientists, rely on graphical devices to help them do their job more effectively. The following graphs are used as “tools of the trade” in offering a parsimonious representation for complex functional relationships among two or more variables.

Graphs of *power functions* (see **Power**) or *operating characteristics* (e.g., Natrella [77]) are used for the evaluation of error probabilities of *hypothesis tests* (see **Hypothesis Testing**) when expressed as a function of the unknown parameter(s). Test procedures are easily compared by superimposing two power curves on the same set of axes. *Sample-size curves* are constructed from a family of operating characteristic curves, each associated with a different **sample size**. These curves are useful in planning the size of an experiment to control the chances of wrong decisions. Natrella [77] offers a number of these for some common testing situations.

Similar contour graphics using families of curves indexed by sample size are also useful for determining confidence limits (see **Confidence Intervals**). These are especially convenient when the endpoints are not expressible in closed form, such as those for the correlation coefficient or the success probability in a Bernoulli sample [78].

Nomographs are graphical representations of mathematical relationships, frequently involving more than three variables. Unlike most graphics, they do not offer a picture of the relationship, but only enable the determination of the value of (usually) any one variable from the specification of the others. Levens [79] discusses techniques for straightline and curved scale nomograph construction. Other statistical nomographs have appeared in the *Journal of Quality Technology*.

Hypothesis Testing

Introduction

Many problems lead to repetitions of an experiment with just two possible outcomes, e.g., (yes, no), (dead, alive), (pass, fail), which reminds us of coin tossing, where we get either heads or tails. Our interest is usually the proportion p of responses. We may estimate p by the observed proportion in our experiments. Often, a theory or hypothesis says that p should have some specific value, and our purpose is to test this hypothesis. To fix our notation, let us speak of coin tossing, where our hypothesis is that the coin is “fair” (i.e., that $p = 1/2$). This is a *statistical hypothesis* since it governs the pattern of outcomes of a series of independent but identical experiments, Bernoulli trials, in fact.

Common sense suggests that if x/n , the observed proportion of heads in n tosses or trials, is near $1/2$, this hypothesis gains support from our data, whereas if x/n is far from $1/2$, we will begin to doubt that $p = 1/2$. Of course, random fluctuations can lead to values of x/n far from $1/2$ even if $p = 1/2$. As n becomes larger, these become less likely, so we should then have a more powerful test. **Probability Theory** enables us to sharpen these ideas. The number of heads, x , in n trials has a *Binomial* distribution (see **Probability Density Functions**) which may be approximated by a *normal* or *Gaussian* distribution with mean np and variance npq , which equal $n/2$ and $n/4$, respectively, for the “null hypothesis” $p = 1/2$. Thus, if the coin is fair, the chance that x will differ from $n/2$ by more than $1.96\sqrt{n/4}$ is fairly accurately $1/20$. For example, if $n = 100$, the probability that x is outside the interval $(50 - 1.96 \times 5, 50 + 1.96 \times 5)$ or roughly $(40, 60)$ when the coin is fair is about 5% or $1/20$. It has become commonplace in science to say that deviations of less than 2σ (2 is an approximation to 1.96 and here $\sigma = \sqrt{n/4} = 5$ is the standard deviation of the approximately normally distributed “statistic” x) are to be expected and so ignored, but that greater deviations are “significant” (i.e., worth looking into; see **Significance Level**). There is nothing sacred about 5%. Scientists use this as a guide – not for making decisions, which depend upon many other factors.

If we have to reach a yes–no decision, where should we draw the line? Clearly, if we knew that

p could never be less than $1/2$, we would only doubt the “ $p = 1/2$ ” hypothesis if x/n were suspiciously larger than $1/2$. A small x/n can only be due to random fluctuations. Thus our test must depend on the *alternative* hypothesis, as well as on the null hypothesis. Again, the (e.g., financial) consequences of saying erroneously that $p = 1/2$ when $p \neq 1/2$ might be much less than of saying erroneously that $p \neq 1/2$ when in fact $p = 1/2$. Then we would want to be very confident before we reject the null hypothesis. Hence the consequences of the decision must play a role. Finally, experiments cost time and money, so we want to make as few as are necessary to reach a “reliable” decision. With “reliable” clearly defined, how many observations are needed? It is clear that we can never be sure that our decision is right, but we can control the probability that it is right. It is also evident that we must be careful if we first look at the data collected before deciding on n – one might be tempted to cheat.

The development of the ideas in the last paragraph comprises the subject matter of *hypothesis testing*, which is intimately connected with a large part of the theory of mathematical statistics, especially **Estimation** (see also **Overview of Statistics; Probability Theory**). Most experiments have more than two outcomes; e.g., they may yield single or multiple measurements whose postulated probability distributions usually depend on several parameters, not just one as we had above. Null and alternative hypotheses may now be more complicated. It is then easy to devise various procedures for testing the same hypothesis. Hence we will need rules for selecting tests.

If one takes a Bayesian view of the general inference problem, hypothesis tests do not arise – all knowledge is summarized in (prior and posterior) probability distributions of the parameters. Classical hypothesis testing seeks only the best control of the probabilities of the two kinds of erroneous decisions, illustrated above, when the null hypothesis and **sample size** are specified beforehand. In *decision theory*, explicit account is taken of the numerical consequences of decisions. *Sequential analysis* studies particularly efficient methods for terminating a sequence of experiments.

Nonparametric methods involve tests that are valid no matter what the distributions of the observations may be. *Multiple testing* theory began with ways of testing hypotheses suggested by the data rather

2 Hypothesis Testing

than being given *a priori*. *Robustness* is concerned with tests that remain sensitive to departures from the null hypothesis when the distribution of the observations falls in some broad class, and so is a sharpened form of nonparametrics that tries to assume nothing.

Early Ideas

As with so much statistics, the early examples are astronomical. An essay in 1734 by Daniel Bernoulli won a prize at the French Academy, which set the following problem: Is the near coincidence of the orbital planes of the planets an accident or a consequence of their creation? Bernoulli invented a test statistic, i.e., a quantity that would be small if the planes were oriented randomly and independently of one another, and large if they were near coincidence. A modern improvement would use the length of the sum of the unit vectors that are perpendicular to each of the planes. Needless to say, in both cases the quantity is far larger than would arise often by chance if the orbits were in independent randomly oriented planes.

Although many tests were invented in the interim, the χ^2 test [1], Student's t -test [2, Paper 2], and Fisher's derivation of the distribution of the **correlation** coefficient opened the modern era of statistics. Many important fields of application for statistics were found in the experimental sciences as well as the world of affairs, since in more and more areas, data were being consciously gathered to investigate specific hypotheses. Many of these experiments were small. Mathematical techniques became available to find the exact probability distributions of many quantities (i.e., statistics) computed from samples. It was then realized that there were many possible tests and estimators in every problem and so a problem of choice. To bring order out of chaos, it was necessary to seek general principles that would tell the statistician which method *should* be used in any given situation.

While Karl Pearson [3] in his book on the scientific method, (*The Grammar of Science* (1892)), had supported the use of Bayes' formula (the principle of inverse probability) to join previous and current data, he rarely used it. His χ^2 statistic,

$$\chi^2 = \sum_{i=1}^k \frac{(x_i - np_i)^2}{(np_i)} \quad (1)$$

tests whether the numbers $x_1, \dots, x_k$ of k types in a sample size n have been drawn from a population whose members are of k types in proportions $p_1, \dots, p_k$. The expected value of x_i is np_i , so χ^2 will be large when at least some of the x_i 's are far from their expectations when we might doubt the hypothesis. If the calculated value is χ_0^2 , he suggested that one should look at P_0 , the probability that samples of n from the multinomial $(p_1, \dots, p_k)$ population would give values of χ^2 greater than χ_0^2 . If we doubt the hypothesis of the given data yielding χ_0^2 , we should also doubt it for data yielding any larger value of χ^2 . He showed how to compute P_0 , the size of which is a measure of the agreement between the data and the assumed distribution $(p_1, \dots, p_k)$. If P_0 is small, we have two explanations – a rare event has happened, or the assumed distribution is wrong. This is the essence of the *significance test* argument. Not to reject the null hypothesis (that the proportions are $p_1, \dots, p_k$) means only that it is accepted for the moment on a provisional basis. "Student" took the same approach for his t -statistic and for r , the correlation statistic [2, Paper 3] with two important asides. First, he remarks that he would prefer to use inverse probability – but does not know how to set his priors. Second, he recognizes that actual samples may not come from normal distributions which he has had to assume, and gives a reason why his t -test might yet be reliable for samples from some nonnormal populations.

By 1925 we find the subject, almost as one finds it today, in Fisher's highly influential book, *Statistical Methods for Research Workers* [4]. The hypothesis being tested, often the *status quo* (so to speak), is the *null hypothesis*. For the fair-coin example, this is $p = 1/2$. If Pearson's χ^2 were applied to testing that a six-sided die was fair, the null hypothesis would be that $p_1 = p_2 = \dots = p_6 = 1/6$. **Significance Level** of 5% and 1% are suggested. Thus, if the P_0 for χ^2 is less than 0.05, it is said to be "significant". Fisher prepared tables to make these and many other significance tests easier to apply by computing the value of the statistic that would need to be exceeded in order that P_0 be less than 0.05, 0.01, and so on. Such numbers are *significance points* of the relevant statistic. In his book, however, **P Values** have not entirely disappeared. It is said that Fisher tabulated significance points rather than P -values only because Karl Pearson held the copyrights to the P -value tables!

By 1925, Fisher [4] had established his theory of point estimation, including the concepts of sufficiency, consistency, efficiency, likelihood, and **Maximum Likelihood**. But he never had a theory of significance test construction, although he invented or developed almost all the common tests, including some basic **Nonparametric Tests** (e.g., use of normal scores, **randomization**, and permutation tests). All his life, Fisher objected in the strongest terms to the use of inverse probability, but clearly felt the need for something like it since he tried to develop his own substitute, fiducial probability. Further, he always thought and wrote as a mathematician applying his skills in areas of basic natural science, but never, for example, in industry, so he was not attracted to decision theory.

Theory, to assess and derive optimal significance tests, was provided in the next 10 years by Neyman and Egon Pearson. The story of their collaboration has been given by Pearson [5]. The key papers are conveniently collected in Neyman [6], Neyman and Pearson [7], and Pearson [8]. Pearson, like “Student”, was interested in the use of statistical procedures to guide routine work in industry where rules of thumb were needed. Neyman brought a more philosophical and formal approach to the problem.

If, for example, the test for the fairness of a coin mentioned above is routinely applied (recall that the **significance level** chosen was 5%), and if “significant” means that we reject the null hypothesis $p = 1/2$, then two kinds of errors may be made. Five percent of the time when p actually equals $1/2$, we will say it does not (i.e., reject the null hypothesis that $p = 1/2$). However, when p is not equal to $1/2$ (e.g., $p = 3/4$), we will sometimes get a number of heads x in n tosses which fall in the range

$$\begin{aligned} & \left((n/2) - 1.96\sqrt{n/4} \right) \\ & (n/2) + 1.96\sqrt{n/4} \end{aligned}$$

If this happens, we will not reject the hypothesis $p = 1/2$ even though it is false. These are called, respectively, *errors of the first and second kinds*. Here, since we are setting up a method for routine application, we imagine that we will always make a definite assertion, or decision, every time. Hence we can talk about long-run rates of erroneous decisions. In nonroutine science, hypotheses do not stand or fall on the results of a statistical test, and this formulation

is less appropriate. The only distinction between significance tests and hypothesis tests seems to be Fisher’s insistence that there is one. Neither gives the weight of evidence for a hypothesis which is perhaps what one might like to have. Significance tests are usually derived or evaluated using the theory of hypothesis testing. It is somewhat ironic that, although Fisher was adamantly opposed to the latter, his tabulations of significant points and his later derivation of nonnull distributions set everything up for hypothesis-testing theory.

In their first paper (1928), Neyman and Pearson defined these errors and investigated an intuitive principle for test construction that yields likelihood-ratio (LR) tests [7]. The latter had appealed to them because Fisher had shown how to use likelihood to obtain “good” estimators and because it arises if one uses the Bayesian approach – which they were reluctant to do. The LR principle (to be explained later) was extraordinarily fruitful; it enabled them to derive all the tests known, including Pearson’s χ^2 , from one rule.

But the nagging question – what is the *best* test? – remained. In 1928, they had implicitly formulated their criterion: keep the rate of errors of the first kind constant, minimize the rate of errors of the second kind. By 1933, all the key definitions had been made to allow an orderly presentation whose centerpiece is the Neyman–Pearson lemma. The subject called *hypothesis testing* has been developed on this basis ever since; the classic text is that of Lehmann [9]. Various other subdisciplines split off as the years went by. The concern that tests should not be dependent on, or insensitive to, distributional assumptions respectively led to distribution-free or nonparametric and robust methods (*see Nonparametric Tests*). Efforts to minimize the cost or sample size in routine sampling led to sequential analysis. The vagueness of the significance level can be resolved if one takes into account the costs of making errors; this led to decision theory. These last two developments are largely due to A. Wald [10] and arose during and after World War II.

The theory of hypothesis testing gradually came to be interpreted rather more rigidly than its originators had in mind. This gave rise to many paradoxes. Practitioners tend to avoid these by less informal usage and *ad hoc* procedures. Some of the paradoxes are eliminated by recognizing that some problems are neither estimation nor testing but an incompletely

4 Hypothesis Testing

formulated activity to do with the discovery of statistical regularities in data. Other paradoxes do not appear in the Bayesian formulation and so have led to its revival and development (*see Overview of Statistics*). However, the key ideas of hypothesis testing will always remain central to the theory of statistics and its applications. We will now define the main concepts needed in the theory in terms of examples since orderly developments are easy to find at a variety of levels of abstraction (e.g., Lehmann [9] and Bickel and Doksum [11]). The paradoxical aspects may be seen in Cox and Hinkley [12]. Barnett [13] gives a general discussion of statistical inference.

The Neyman–Pearson Lemma

In the binomial and multinomial examples above, the data is a sample from a distribution fully specified on the null hypothesis; i.e., on the null hypothesis the probability of the sample is uniquely determined. However, there are many alternative hypotheses (e.g., $p \neq 1/2$ for the binomial case). We say then that the null hypothesis is *simple* and the alternative is *composite*.

Had the data been a sample from a Gaussian distribution with mean μ and variance σ^2 , a common null hypothesis is $\mu = 0$, with σ^2 unspecified. This null hypothesis is composite. To test $\mu = 0$, one instinctively thinks of rejecting the null hypothesis if $\bar{x}$ differs too much from zero. But use of the median makes sense, too. Which is better? Also, here we can speak of the probability density rather than the probability of the data; let “probability function” or “likelihood” denote either.

The problem may be stated fairly generally now. Suppose that the probability function of the data $\mathbf{x}$ is $p(\mathbf{x}; \theta)$, where $\mathbf{x}$ is a point in the *sample space* $\mathcal{X}$ and θ is a point in the parameter space Θ (*see Probability Theory*). Define the null hypothesis by $\theta \in \Theta_0 \subset \Theta$ and the alternative hypothesis by $\theta \in \Theta_1 \subset \Theta$, ($\Theta_0 \cap \Theta_1 = \emptyset$). In the binomial case $\mathcal{X} = \{0, 1, \dots, n\}$ and $\theta = p$, $\Theta = \{p | 0 \leq p \leq 1\}$, $\Theta_0 = \{1/2\}$, $\Theta_1 = \{p | p \neq 1/2\}$. We will sometimes use H_0 and H_1 for the null and alternative hypothesis. In the examples, we rejected the null hypothesis when $\mathbf{x}$ fell in a set such that some function, the test statistic, say $t(\mathbf{x})$, of the data took too extreme a value. This means that any test divides $\mathcal{X}$ into two mutually exclusive

regions; R , the rejection or critical region and its complement, the acceptance region. Choosing a test is choosing a test statistic $t(\mathbf{x})$ or equivalently a region R . For the test to have **Significance Level** α (e.g., 0.05), we require R such that

$$\Pr(\mathbf{x} \in R | \theta \in \Theta_0) \leq \alpha \quad (2)$$

This ensures that, although the left-hand side of equation (2) may vary as θ takes different values in Θ_0 , the probability of type 1 errors, or false alarms, never exceeds α . Now there will usually be many such regions R , so we want to find one that will maximize

$$\Pr(\mathbf{x} \in R | \theta \in \Theta_1) \quad (3)$$

This probability, for a fixed R , is a function of θ , the **Power** function of the test R . It is the probability of rejecting the null hypothesis, which is what we want to do when $\theta \in \Theta_1$, the alternative hypothesis. Hence maximizing equation (3) is the same as minimizing the probability of errors of the second kind.

To progress with this general formulation, we consider the simplest case when $\Theta_0 = \{\theta_0\}$, $\Theta_1 = \{\theta_1\}$ (i.e., both the null and alternative hypotheses are simple). Then the problem posed by equations (2) and (3) is as follows: find R such that

$$\int_R p(\mathbf{x}, \theta_0) d\mu(\mathbf{x}) \leq \alpha \quad (4)$$

$$\int_R p(\mathbf{x}, \theta_1) d\mu(\mathbf{x}) = \max \quad (5)$$

It is clearly advantageous to have equality in equation (4). This is usually possible except for discrete distributions (see below). Assume that there are many regions R satisfying equation (4) with equality. To achieve the maximum required in equation (5) we would want to choose points for R where $p(\mathbf{x}, \theta_1)$ is relatively large but where $p(\mathbf{x}, \theta_0)$ is relatively small. This suggests that the optimal R might be R , the set of points $\mathbf{x}$ where the ratio of $p(\mathbf{x}, \theta_1)$ to $p(\mathbf{x}, \theta_0)$ is greatest, i.e.,

$$\frac{p(\mathbf{x}, \theta_1)}{p(\mathbf{x}, \theta_0)} \geq k \quad (6)$$

where k is chosen so that equation (4) is satisfied. Then R and R both satisfy equation (5), but

$$\int_{R^*} p(\mathbf{x}, \theta_1) d\mu(\mathbf{x}) \geq \int_R p(\mathbf{x}, \theta_1) d\mu(\mathbf{x}) \quad (7)$$

since in the part of R not intersecting R , $p(\mathbf{x}, \theta_1) \geq kp(\mathbf{x}, \theta_0)$, while in the part of R not intersecting R , $p(\mathbf{x}, \theta_1) \leq kp(\mathbf{x}, \theta_0)$. This is the Neyman–Pearson lemma – the *most powerful test* of θ_0 versus θ_1 is based on the LR region (6).

Example 1 Let x be binomial (n, p) , the null hypothesis $p = p_0$, and the alternative hypothesis $p = p_1 > p_0$. The LR is

$$\frac{\binom{n}{x} p_1^x (1-p_1)^{n-x}}{\binom{n}{x} p_0^x (1-p_0)^{n-x}} = K \left(\frac{p_1/(1-p_1)}{p_0/(1-p_0)} \right)^x \quad (8)$$

Because $p_1 > p_0$, this ratio increases with x so that the critical region is $\{c, c+1, \dots, n\}$ when we choose c to make

$$\sum_c^n \binom{n}{x} p_0^x (1-p_0)^{n-x} \quad (9)$$

as near to α as possible. Had p_1 been less than p_0 , the critical region would have been in the lower tail of the distribution. Both tests are as intuition would suggest; $p_1 > p_0$ is a one-sided alternative hypothesis and we have a one-tailed test.

To get α exactly here, we must resort to *randomization*. For example, if $n = 10$, $p_0 = 1/2$, $\alpha = 0.05$, and $p_1 > 1/2$, observe that $\Pr(6 \text{ heads}) = 28/256$, $\Pr(7 \text{ heads}) = 8/256$, and $\Pr(8 \text{ heads}) = 1/256$. Consider the following rule:

If we get 6 heads, reject with probability δ ;
if we get 7 or 8 heads, reject with probability 1.

Then

$$\Pr(\text{reject} | p = \frac{1}{2}) = \frac{28\delta + 8 + 1}{256} = \frac{1}{20} \quad (10)$$

if $\delta = 19/140$. For this reason, the general theory does not use a critical region but a function $\phi(\mathbf{x})$, the probability of rejection given sample $\mathbf{x}$. In the simplest case, $\phi = 1$ or 0 and is the indicator function of the critical region.

The example shows another special feature. When the alternative to $p = p_0$ is $p_1 > p_0$, the *same* test is also optimal for all $p_1 > p_0$, and is said to be *uniformly most powerful* (UMP), clearly a most desirable property. However, had the alternative been $p \neq p_0$, a two-sided alternative, this argument fails. Clearly, we need to have two-tailed tests (i.e., some of each tail in the critical region), but we need a theory to tell us how much of each.

Finally, had the null hypothesis been $p \leq p_0$ (composite) and the alternative $p \geq p_1 > p_0$, the same test may be shown to be UMP.

Example 2 Let $X_1, \dots, X_n$ be independent and Gaussian (μ, σ^2) with *known* σ^2 , and the null and alternative hypotheses be $\mu = \mu_0$, $\mu = \mu_1$, respectively. The LR is

$$\frac{(\sqrt{2\pi}\sigma)^{-n} \exp\{-\sum (x_i - \mu_1)^2 / 2\sigma^2\}}{(\sqrt{2\pi}\sigma)^{-n} \exp\{-\sum (x_i - \mu_0)^2 / 2\sigma^2\}} \quad (11)$$

which reduces to

$$\exp\{(n/2\sigma^2)[(\mu_1 - \mu_0)\bar{x} - \mu_1^2 + \mu_0^2]\} \quad (12)$$

Thus, if $\mu_1 > \mu_0$, the ratio is large for large positive $\bar{x}$, so the critical region is $\bar{x} > c$. To calculate c we observe that on the null hypothesis $\mu = \mu_0$, $(\bar{x} - \mu_0)/(\sigma/\sqrt{n})$ is standard Gaussian, so the $\alpha = 0.05$ test is to reject if $\bar{x} > \mu_0 + 1.64\sigma/\sqrt{n}$. Once again this is a UMP test for all $\mu_1 > \mu_0$. The reader may observe that $\bar{x}$ is here a *sufficient statistic* for μ , so we would expect the best test to use it.

The power function of this test is, by definition,

$$\begin{aligned} \Pr(\bar{x} > \mu_0 + 1.64\sigma/\sqrt{n} | \mu) \\ = \Pr\left(z = \frac{\bar{x} - \mu}{\sigma/\sqrt{n}} > \frac{\mu_0 - \mu}{\sigma/\sqrt{n}} + 1.64\right) \end{aligned} \quad (13)$$

where $z = (\bar{x} - \mu)\sqrt{n}/\sigma$ now has a standard Gaussian distribution. As a function of μ , the power goes from zero at $\mu = -\infty$, to 0.05 at $\mu = \mu_0$, and to unity as μ increases to infinity.

A statistician is often asked: *How big a sample should be taken?* In the example above, if one can guess σ from previous experience, has settled on a 5% test, and is willing to pay what it costs to get a power of, say 0.90 to detect some particular μ , then equation (13) and the normal tables will provide the value of n that is needed (*see also Sample-Size Determination*). This value will increase as μ gets closer to μ_0 or as desired power is increased.

The power function (equation 13) for fixed n is a monotonically increasing function of μ . The power functions of other plausible tests (e.g., one that uses the sample median instead of the mean) will also increase. But at no value of μ can any of these curves ever rise above the curve given by equation (13)! It is the envelope of all possible power curves

6 Hypothesis Testing

for this problem. This illustrates graphically how our test is optimal. If there were no UMP test, no one power function would always be best (i.e., greatest for every μ).

Example 3 Let $X_1, \dots, X_n$ be independent and identically (i.i.d.) with the Cauchy density $\pi^{-1}(1 + (x - \theta)^2)^{-1}$; let the null hypothesis be θ_0 and the alternative be $\theta_1 > \theta_0$. The LR no longer simplifies – there is no single sufficient statistic for θ . The value of the L.R. for any sample depends on the values of both θ_0 and θ_1 . Finding the value of k to get a test of size α would probably involve applying the central limit theorem to the logarithm of the LR.

There is no UMP test – θ_1 always occurs in the test statistic.

A strategy often invoked in such cases is to seek the limit of the foregoing test as $\theta_1 \downarrow \theta_0$ – the *locally most powerful* (LMP) one-sided test. Using the general notation, the logarithm of the LR is

$$\log p(\mathbf{x}, \theta_1) - \log p(\mathbf{x}, \theta_0) \quad (14)$$

When θ is real, and θ_1 is near θ_0 , this is approximately proportional to

$$\partial \log p(\mathbf{x}, \theta_0) / \partial \theta_0 \quad (15)$$

and large values of this will be the LMP test of θ_0 *versus* values of θ just greater than θ_0 . Alternatively, if one thinks of all the possible power functions for tests of θ_0 *versus* $\theta > \theta_0$ and chooses the test whose slope is greatest at the origin, one again derives the test statistic equation (15). When the power of a test based on $\mathbf{R}$ is

$$\gamma(\theta) = \int_R p(\mathbf{x}, \theta) d\mu(\mathbf{x}) \quad (16)$$

the slope at θ is given by

$$\gamma'(\theta_0) = \int_R \frac{\partial p}{\partial \theta_0}(\mathbf{x}, \theta_0) d\mu(\mathbf{x}) \quad (17)$$

A similar argument to that leading to the Neyman–Pearson lemma tells us here that $\gamma'(\theta_0)$ will be a maximum, subject to $\gamma(\theta_0) = \alpha$ if R is based on large values of

$$\frac{1}{p(\mathbf{x}, \theta_0)} \frac{\partial p(\mathbf{x}, \theta_0)}{\partial \theta_0} = \frac{\partial}{\partial \theta_0} \log p(\mathbf{x}, \theta_0) \quad (18)$$

as we have just seen.

In the Cauchy case above, the LMP test is based on large values of

$$t(\mathbf{x}) = \sum_{i=1}^n \frac{x_i - \theta_0}{1 + (x_i - \theta_0)^2} \quad (19)$$

The asymptotic distribution of $t(\mathbf{x})$ is easily obtained from the central limit theorem.

Thinking again in terms of the graph of the power function, suppose that we have a two-sided alternative $\theta \neq \theta_0$ and attach equal importance to small deviations above and below θ_0 . It is then natural to seek a critical region R such that

$$\gamma(\theta_0) = \alpha, \gamma'(\theta_0) = 0, \gamma''(\theta_0) = \text{maximum} \quad (20)$$

A Neyman–Pearson type of argument then tells us that the optimal critical region is the set of points $\mathbf{x}$ such that

$$\frac{\partial^2 p(\mathbf{x}, \theta_0)}{\partial \theta_0^2} \geq k_1 \frac{\partial p(\mathbf{x}, \theta_0)}{\partial \theta_0} + k_2 p(\mathbf{x}, \theta_0) \quad (21)$$

Such a test is said to be an LMP *unbiased* test. If applied to Example 2, it leads to the 5% level test; reject if

$$\frac{|\sqrt{n}(\bar{x} - \theta_0)|}{\gamma} > 1.96 \quad (22)$$

the equal-tailed version of the UMP (and hence LMP) test for one-sided alternatives. If applied to Example 3, it does not lead to the two-sided version of the LMP test given above.

When only one parameter is involved, much more theory is available, but most real problems involve several parameters.

Several-Parameter Problems

Difficulties arise when dealing with problems involving several parameters. The null hypothesis is usually composite. To have a fixed significance level, we need a rejection region that is *similar* to the whole sample space in that its probability content is constant on H_0 . Parameters left unspecified by H_0 are *nuisance parameters*. Even if the null hypothesis is simple, the power function of a test will vary with all the parameters. One wants it to increase rapidly in all directions away from its value at θ_0 . But sacrificing slope in one direction

may increase it in another! This dilemma can be resolved only by weighing the importance of each direction, according to its consequences. These difficulties were recognized very early. As a practical matter, one may use an extension of the LR, or asymptotically equivalent procedures involving maximum-likelihood estimators. There is, however, a great deal of elegant theory of optimal tests when they exist.

Example 4 Let $X_1, \dots, X_n$ be independent and Gaussian (μ, σ^2) and let the null hypothesis be $\mu = \mu_0$ and the alternative $\mu \neq 0$. Here σ^2 is unspecified and so is a nuisance parameter. Ignoring constants,

$$\log \text{likelihood} = -n \log \sigma - \frac{1}{2\sigma^2} \sum (x_i - \mu)^2 \quad (23)$$

Maximizing over all values of μ we find $\hat{\mu} = \bar{x}$, and over all values of $\sigma^2 > 0$ it yields

$$\begin{aligned} \max_{H_1}(\log \text{likelihood}) \\ = -\frac{n}{2} \log \frac{\sum (x_i - \bar{x})^2}{n} - \frac{n}{2} \end{aligned} \quad (24)$$

If we set $\mu = \mu_0$ in equation (23) and maximize, we find that

$$\begin{aligned} \max_{H_0}(\log \text{likelihood}) \\ = -\frac{n}{2} \log \frac{\sum (x_i - \mu_0)^2}{n} - \frac{n}{2} \end{aligned} \quad (25)$$

Forming the log-likelihood ratio of Neyman and Pearson but after these maximizations (i.e., dividing equation 24 by equation 25), we get

$$-\frac{n}{2} \log \left(\frac{\sum (x_i - \bar{x})^2}{\sum (x_i - \mu_0)^2} \right) \quad (26)$$

Hence

$$\begin{aligned} + 2 \log \text{L.R.} \\ = -n \log \left\{ \frac{1}{1 + n(\bar{x} - \mu_0)^2 / \sum (x_i - \bar{x})^2} \right\} \end{aligned} \quad (27)$$

will be large if

$$t^2 = \frac{n(\bar{x} - \mu_0)^2}{\sum (x_i - \bar{x})^2 / (n-1)} \quad (28)$$

the square of Student's t , is large. Note that for large n , equations (27) and (28) are essentially equal. The null distribution of t does not contain σ^2 , so the t -test has similar rejection regions.

Had we done the same in the case of known σ^2 , we would have obtained

$$2 \log \text{L.R.} = n(\bar{x} - \mu_0)^2 / \sigma^2 \quad (29)$$

which on the null hypothesis has a χ^2 distribution with 1 degree of freedom. The same is asymptotically true of t^2 and so of equation (27). This illustrates *Wilks theorem*, which says roughly that as $n \rightarrow \infty$, $2 \log \text{LR}$ has a χ^2 distribution whose **degrees of freedom** are equal to the number of parameters specified by the null hypothesis.

The Pearson χ^2 test may be shown to be an approximation of an LR test. It also produces an answer when the null hypothesis specifies several parameters, unlike Examples 3 and 4.

Example 5 Reconsider Example 4. There are two unknown parameters μ and σ^2 and $\bar{x}$ and $s^2 = \sum (x_i - \bar{x})^2 / (n-1)$ are sufficient statistics for them. It follows from the theory of sufficiency that any good test will only use these two summaries of the data. Further, any test should be unchanged if we measure the x 's from a new origin and on a new scale (e.g., if they are temperatures, switch from Fahrenheit to Celsius). $\bar{x} - \mu$ and s^2 are independent of origin and $(\bar{x} - \mu)/s$ is also independent of scale. Thus, by demanding that our test should depend upon sufficient statistics and be *unchanged* under the natural group of transformations (here scale and location) which leave the problem unchanged, we arrive at the t -test. Among such invariant tests, we may now show that it has UMP properties, as in Example 2. Essentially, by invoking these general principles, we are able to reduce this problem so that the Neyman-Pearson lemma can be applied.

For a long time **nonparametric tests** remained outside the Neyman-Pearson theory – note that all the examples above are parametric. However, by requiring invariance under the group of symmetries of the problem, they were united with optimal **parametric tests**.

Example 6 Test that the cumulative distributions F and G are identical (i.e., $F(x) = G(x)$), given samples $(X_1, \dots, X_m)$ and $(Y_1, \dots, Y_n)$ from F and G .

When nothing is known of the common distribution, our test should be invariant under all monotonic transformations since they preserve the identity of F and G . Hence permissible tests can only depend on the ranks of the X and Y observations in the list of $m + n$ observations. Within this class of tests we can select members by Neyman–Pearson methods if we define specific alternatives to $F = G$; for example, that $G(x) = F(y - \Delta)$, $\Delta \geq 0$. If F is the logistic distribution, this line of argument may be used to prove that the Wilcoxon test is LMP.

One of the most surprising discoveries in the whole theory is that one need *not* pay a great price in power in order to buy a reliable significance level. To prove such assertions, one needs to introduce a definition of test efficiencies, e.g., asymptotic relative efficiency.

Example 7 Suppose that X_i are independently normal with means μ_i and variances σ^2 ($i = 1, \dots, n$) and that we have an independent estimate s^2 of σ^2 , distributed as $\sigma^2 \chi_f^2 / f$. To test a prespecified hypothesis $\sum_1^n C_i \mu_i = 0$ with $\sum_1^n C_i = 0$, we would refer $\sum C_i X_i / \left(s \sqrt{\sum C_i^2} \right)$ to the t -distribution with f degrees of freedom. If, however, we began inventing such hypotheses *after* we had looked at the data, this method would be improper (e.g., we might seek the largest difference $X_i - X_j$, which certainly is not normal with mean zero and variance two).

We may allow for all such possible comparisons of the μ_i 's by using the Cauchy inequality

$$\left\{ \sum_1^n C_i X_i = \sum C_i (X_i - \bar{X}) \right\}^2 \leq \sum_1^n C_i^2 \sum_1^n (X_i - \bar{X})^2 \quad (30)$$

so that

$$\frac{(\sum C_i X_i)^2}{\sum C_i^2 (s^2)} \leq \frac{\sum_1^n (X_i - \bar{X})^2}{s^2} \quad (31)$$

The left-hand side (lhs) is the square of our original statistic, and the rhs is $(n - 1)$ times a variable distributed as F with $n - 1$ and f degrees of freedom, which may thus be used to make a proper test. If, at the outset, we agree to look only

at differences of pairs, a different and more stringent procedure is available.

In the inspection of data one often wants to make a rough test to see if some aspect of it is exceptional, and similar care is always required, although it is rarely possible to formulate the problem as precisely as above. Tukey has called this the *multiplicity problem*.

Miscellaneous Remarks

The account above gives only the simplest cases of the basic ideas and is biased toward application. Through the references and other entries, especially **Parametric Tests; Nonparametric Tests; Normality Tests; Power; P Values; Significance Level; Overview of Statistics and Probability Theory**, the reader may find descriptions of those further aspects he or she seeks. The reader is fortunate that almost all the key papers have been collected, and most still make fascinating reading. Any such study will take the reader deeply into estimation theory and the mathematical structure of probability distributions.

On logical issues, not even hinted at here, Cox and Hinkley [12] is recommended. The role of conditionality is particularly puzzling. Neyman–Pearson theory is centered on maximizing power and uses all conceivable samples. But there are often aspects of the sample that do not depend on the parameter being tested, and a good case may be made for considering only all samples with the same such aspects as our given sample. But these two principles may be conflicting. One is often tempted to use conditional tests to eliminate nuisance parameter difficulties. One practical topic closely related to hypothesis testing but not even mentioned above is interval estimation (*see Confidence Intervals*). This arises when tests are examined to find the set of parameter values which cannot be rejected as null hypotheses. Lack of space prevents any discussion of robust tests.

Some of these logical conundrums are eliminated by adopting a Bayesian approach to inference, which, however, brings its own difficulties. Cox and Hinkley [12] give a brief discussion (*see also Overview of Statistics*). Box and Tiao [14] illustrate the Bayesian handling of many common statistical models. Box [15] attempts a partial synthesis of Bayesian and classical inference in which

significance tests are used for model checking (model to data) but Bayesian methods are used for estimation (data to model).

Maximum Likelihood

Introduction

The term *maximum likelihood* refers to a general method of **Estimation** with important historical and practical significance. Consider a sample $y_1, y_2, \dots, y_n$ drawn independently from a distribution with density or probability function $f(y; \theta)$ with an unknown vector parameter θ . The likelihood function is defined as

$$L(\theta) = \prod_{i=1}^n f(y_i; \theta) \quad (1)$$

The maximum-likelihood estimate (MLE) is the value $\theta = \hat{\theta}$ which maximizes $L(\theta)$ over the set of all possible values for θ . In practice, it is usually more convenient to maximize the logarithm of the likelihood function, $l(\theta) = \ln L(\theta)$. From calculus, it follows that $\hat{\theta}$ satisfies the score equation $\partial l / \partial \theta = 0$.

Early references to the method of maximum likelihood are attributed to Gauss, Laplace, and Edgeworth [1]. However, the prominent English statistician R. A. Fisher is unquestionably responsible for popularizing the technique and for identifying many of its statistical properties [2].

The method has a strong heuristic appeal: choose as your parameter estimate the one which makes the observed data seem most likely. As it turns out, it is often the best estimate possible, particularly in large samples. Inference is made easy by the fact that MLEs are consistent and asymptotically normal under broad regularity assumptions, with a variance that can be estimated from the observed or expected information matrix. The MLE is also invariant under one-to-one transformations of the parameters, so to obtain the MLE of a transformation of the original parameters, one need only apply the transformation to the original MLE.

Optimal Properties

The following is a list of the most important properties of the MLE in large samples (i.e., $n \rightarrow \infty$):

1. Consistency

The MLE converges in probability to the true value of the parameter (i.e., for any $\epsilon > 0$, $\lim_{n \rightarrow \infty} P(|\hat{\theta}_n - \theta| > \epsilon) = 0$).

2. Asymptotic normality

The distribution of $n^{1/2}(\hat{\theta} - \theta)$ converges to a **normal distribution** with zero mean and a **covariance** matrix which is the inverse of the information matrix $\mathbf{I}$. From a practical point of view it is more convenient to say that $\hat{\theta}$ is approximately distributed as $N(\theta, \mathbf{I}^{-1}/n)$.

3. Asymptotic efficiency

The MLE is the best asymptotically normal estimate in terms of its variance in large samples. Put more precisely, if $\tilde{\theta}$ is another estimate such that $n^{1/2}(\tilde{\theta} - \theta) \xrightarrow{\mathcal{L}} N(\theta, \mathbf{C})$, where $\mathbf{C}$ is a fixed matrix, then $\mathbf{C} \geq \mathbf{I}^{-1}/n$ in the sense that $\mathbf{C} - \mathbf{I}^{-1}/n$ is a positive semidefinite matrix.

Regularity Conditions

It is important to be aware of the general regularity conditions for the optimal properties of the MLE. Most advanced statistics texts have a discussion of these conditions [3, 4], with the classic reference being Cramér [5]. The following three conditions are commonly given:

1. The observed data points $y_1, y_2, \dots, y_n$ are independently and identically distributed (i.i.d.) according to a density or probability function $f(y; \theta)$, where θ has finite dimension m . This condition is less restrictive than it may seem, given that y_i may be a vector. In fact, the method of maximum likelihood is popular and appropriate for many regression problems where the distributions of the data points are not identical, and many texts give less restrictive assumptions.
2. The underlying density or probability function is identifiable, that is, $f(y; \theta_1) = f(y; \theta_2)$ for all y implies that $\theta_1 = \theta_2$.
3. The density is “smooth” in the sense that f has derivatives up to the third order with finite expectation, and the information matrix

$$\mathbf{I} = E_{\theta} \left[\frac{\partial^2 \ln f(y; \theta)}{\partial \theta_j \partial \theta_k} \right], \quad j, k = 1, \dots, m \quad (2)$$

exists and is nonsingular. The latter conditions ensure that the asymptotic covariance matrix exists.

These conditions are satisfied for many models of interest, such as the binomial, normal, and Poisson distributions (see **Probability Density Functions**).

Maximum-Likelihood Calculations

Maximum-likelihood **estimation** involves finding a global maximum of a function of one or several parameters. For certain models, the solution can be expressed as a simple function of the data. However, more often the solution must be posed as a nonlinear optimization problem. Typically, it involves solving a system of nonlinear equations.

The main methods in use today are the Newton–Raphson (NR) or quasi-Newton (QN) methods, and the Fisher scoring (FS) algorithm [6]. The NR algorithm is based on an approximation of the log likelihood by a quadratic function through a Taylor series expansion of the score functions. To implement the NR algorithm, one has to provide second-order derivatives for the log-likelihood function – the so-called Hessian matrix. Initial values for the parameters are updated and the process is repeated until convergence is obtained. If the initial value for parameters is close enough to the maximum, the NR algorithm usually converges quickly. However, if the initial value is poorly chosen it may fail. In particular, the Hessian matrix can become a nonpositive-definite. Upon convergence, at the final iteration, the inverse of the Hessian matrix provides an approximation to the asymptotic covariance of the MLE. In the QN algorithm only the first derivatives are used, and the second derivatives are estimated on the basis of the results from previous iterations. The QN algorithm involves line search methods, that is, maximization of the log likelihood along a given ray in the parameter space.

The difference between the NR and FS algorithms is that the latter uses the expectation of the Hessian matrix rather than the Hessian matrix itself, as in the NR algorithm. There are two versions of the FS algorithm. In the first version, the expectation of the Hessian matrix is approximated as the sum of cross-products of first derivatives. In the second version, the exact calculated information matrix is used. Thus, to use this version of the FS algorithm one has to have a formula for the information matrix as a function of the parameters calculated prior to the maximization procedure.

Other methods are sometimes used for maximum-likelihood estimation. One that deserves special mention is the EM (expectation–maximization) algorithm. Certain likelihoods may be thought as involving missing data, with the most notable example being random effects models. The EM method works in this setting by maximizing the expectation of the log-likelihood iteratively for the complete data. This may aid in difficult maximization problems by taking advantage of simple closed-form solutions available for the “M” stage. Other advantages of the **EM algorithm** include its natural statistical interpretation and its property of producing an increasing sequence of log likelihood values in the specified parameter space. The principal drawback is that it may be relatively slow.

Example: Estimation of a Proportion

We observe the occurrence of a certain event for n individuals, where y_i is 1 if the event occurs and 0 otherwise. It can be assumed that events are independent among individuals and have the same probability of occurrence θ . The likelihood can be written as

$$L(\theta) = \prod_{i=1}^n \theta^{y_i} (1 - \theta)^{1-y_i} = \theta^m (1 - \theta)^{n-m} \quad (3)$$

where m is the number of events observed among the n individuals. The log likelihood is

$$l(\theta) = m \ln(\theta) + (n - m) \ln(1 - \theta) \quad (4)$$

To find the maximum, we consider the following score equation:

$$\frac{dl}{d\theta} = \frac{m}{\theta} - \frac{n - m}{1 - \theta} = 0 \quad (5)$$

which has the unique solution $\hat{\theta} = m/n$.

Discussion and Extensions

In theory, the method of maximum likelihood is very simple: determine an appropriate sampling distribution for the data, write down the likelihood as a function of the unknown parameters, and solve for the estimate. Of course, in practice it is not always so easy. Solutions to the likelihood score equations

usually must be arrived at by numerical methods, and may be computationally intensive or inaccurate. For some models and data sets it may be difficult to demonstrate that the likelihood has a unique global maximum. Many small-sample MLEs can be shown to be biased (*see* **Bias of an Estimator**). The presence of nuisance parameters can exacerbate the computational difficulties. Often the MLE is quite nonrobust to **Outliers** and, unlike competing general methods such as **Least-Squares Estimation** and the method of **moments** (*see* **Estimation**), computation of the MLE requires that the distribution of the data be completely parameterized. Uniformly minimum variance unbiased (UMVU) theory and Bayesian methods compete with maximum-likelihood estimation with regard to optimal properties, but also require complete specification of the distribution, and may be even harder to implement.

To overcome some of the difficulties of maximum-likelihood estimation, modified methods have been proposed such as restricted maximum likelihood (REML), conditional likelihood, pseudolikelihood, quasi-likelihood, partial likelihood, and M estimation. These methods were all inspired by the powerful

heuristic appeal and conceptual simplicity of the original formulation of the method of maximum likelihood.

Missing Data and Imputation

Introduction

Missing data is a comprehensive term that comprises various aspects of incomplete information on the studied variables. An example of incomplete information is a longitudinal study of consumer satisfaction, with several surveys performed over a period. The data on consumer satisfaction is obtained by interviewing a sample from the customers' population.

1. Some of the customers from the intended sample may refuse to participate in the study. At the analysis stage, the information from those individuals will be missing on all the items and in all the subsequent surveys. This type of missing data is a *unit nonresponse* for all the surveys in the study.
2. Some customers may participate in initial studies but drop out from the study afterwards. In this attrition case with dropouts, the missing data is a still considered a *unit nonresponse* but only for the late surveys in which they do not participate.
3. In each particular survey, respondents may decide not to respond to specific question, e.g. when questions are sensitive, or the respondent ends the interview before its completion. The resulting data thus contains *item nonresponses*. Item nonresponse may also occur when respondents have no opinion or knowledge on issues, and the questions do not contain categories to cover such eventualities. Furthermore, if the respondents provide information that does not pass the logical tests (e.g. outside allowable range), the data will be again coded as *item nonresponse*.
4. Incomplete information may also result from *partial recording*. Examples of such partial recording are values known to be outside prespecified limits, or data with *interval censoring*, which are known to be between specific values.
5. In the **quality control** settings, *partial recording* may occur when the data are *batched* and the available information pertains to the entire batch rather than to the individual observations. Such partial recordings are missing data by design. A

different type of partial recording by design can occur when a subset of the data is subjected to more expensive measurements, while the values for the rest of the data are obtained by a simpler and more error-prone method of measurements.

In sample surveys, unit and item nonresponses can hardly be avoided and are an integral part of any study (see **Design and Testing of Questionnaires; Data Management in Survey Sampling**). In the quality control settings, efforts to avoid missing data can be more successful and typically rely on improved technology (see **Control Charts and Process Capability**). In multivariate process control, the problem is amplified since measurements can be derived from several measurement systems that have different levels of uncertainty and operate at difference cycle times (see **Multivariate Control Charts Overview; Statistical Process Control, Multivariate**). In clinical trials, participants who drop out of the study for any reason cause missing data (see **Case-Control Studies; Disease and Clinical Trial Modeling**). In designed experiments, some replicates or experimental runs might have not been executed causing another type of missing data (see **Factorial Experiments; Screening Designs; Response Surface Methodology**). Methods of dealing with missing data typically cannot overcome the impact of missing data and yield less accurate results than what can be achieved with datasets collected on all the intended units and items. Indeed, as mentioned by one of the leaders in the research on missing data "the most important step in dealing with missing data is to try to avoid it during the data-collection stage" [1].

In many cases, the transformation of the sets of data containing missing observations into a complete dataset precedes the analyses aimed at assessing the parameters of the data. The two basic methods for transforming the dataset into a rectangular array to be analyzed are as follows:

1. discard the incomplete cases and then analyze the units with complete information (complete-case analysis), or
2. impute estimated values instead of the missing ones and then analyze the filled in data.

In the longitudinal study of consumer satisfaction example, for each survey separately, missing data have to be considered in the analysis, usually by

2 Missing Data and Imputation

properly weighting the observed items. Alternatively, incomplete data can be analyzed by more sophisticated methods which do not require a complete dataset. In some cases, the common practice is to perform a basic comparison between the characteristics of the units (say, respondents) with complete observations and the characteristics of the units with incomplete data.

The pattern of the missing data defines the observed and the missing values in the dataset. Especially in longitudinal studies, when the missing data are due to attrition and dropout, the pattern of missing data contains important relevant information for analysis. Another important pattern is the univariate item nonresponse, i.e. missing data on a single variable with complete data on all the others.

The Process that Causes Missing Data and the Data Analysis

The process that causes missing data is related to the possible relationship between the fact that an observation is missing and the values of observations. When analyzing the data, while we consider the observed pattern of missing data, we almost always ignore the process that caused the data. As Rubin [2] mentioned, “When making sampling distribution inferences about the parameter of the data, θ , it is appropriate to ignore the process that causes missing data if the missing data are ‘missing at random’ and the observed data are ‘observed at random’, but these inferences are generally conditional on the observed pattern of missing data”.

The terms *missing at random* (MAR) and *missing completely at random* (MCAR) are fundamental in defining the possible relationship between the fact that an observation is missing and the values of observations. In this context, values of observations refer both to the values of the observed data (call them Y_{obs}) as well as to the potential values of the missing data (call them Y_{miss}). Let Y denote all the observations, observed or missing, with Y_{ij} being the variable j on the i th observation. The terms *MAR* and *MCAR* concern the relationships between those values and the distribution of the random matrix M of missing data indicators, (i.e., $m_{ij} = 1$ is variable j on observation i is missing, and 0 otherwise).

Missing data are MCAR, if the conditional distribution of M may depend on the unknown

parameters of the data Θ but not on Y_{obs} or Y_{miss} . Then, if the data are MCAR, the conditional distribution of M satisfies

$$f(M|Y, \Theta) = f(M|\Theta) \text{ for all } Y \text{ and } \Theta \quad (1)$$

In the consumer survey example, data on specific items will be MCAR if, say, individuals may decide by a random drawing whether to reply to some questions, with possible different probabilities of replying in the various subpopulations. Also, unit nonresponse may be completely at random, if again, individuals may decide by a random drawing whether to participate in the study, with possible different probabilities of participation in the various subpopulations.

Missing data are MAR, if the conditional distribution of M may depend on Θ and Y_{obs} but not on Y_{miss} . Thus, if the data are MAR, the conditional distribution of M satisfies

$$f(M|Y, \Theta) = f(M|Y_{\text{obs}}, \Theta) \text{ for all } Y_{\text{miss}} \text{ and } \Theta \quad (2)$$

In the longitudinal consumer study example, MAR will occur if say, the customers’ decision regarding participation in the survey at time t , depends on the grade that they assigned in the previous surveys, but not on the grades that they would have assigned at this survey. Again, the probabilities of participations may also vary in the various subpopulations. Obviously, since in the unit nonresponse there are no Y_{obs} , there is no MAR for an entire unit.

All other cases of missing data are not missing at random (NMAR). As an example, let two units have equal observations on all but one variable, with one unit having data and the other not having data on the remaining variable. If missing data are NMAR, the two units differ systematically on that remaining variable. In terms of the conditional distribution of M , the fact that the data is missing is affected by the unobserved value.

Handling of Missing Data – Listwise Deletion and Weighting

In most of the cases, the process that causes missing data is unknown. However, by using various methods of handling missing data, which ignore either only the process that causes missing data or both the process as well as the pattern of the observed data, the investigator implicitly assumes a certain mechanism that caused the missing data.

The simplest method of handling missing data is to discard the incomplete cases and then analyze the units with complete information “as is”. This complete-case analysis is thus preceded by what is known in the computer software as a *{listwise deletion}*. This method of handling missing data is indeed simple and quite common. As an example, in a study [3] the investigators collected data on more than 500 companies from the United Kingdom and aimed at creating an algorithm that can be used in the formulation of a knowledge-based decision system. They mentioned that “prior to conducting the statistical analysis, cases with missing data were eliminated from the dataset”.

This type of complete-case analysis ignores both the mechanism that created the missing data as well as the observed pattern of missing data. When the observed pattern of missing data is ignored, MAR is not a sufficient assumption. The required assumption in this case is MCAR. Under the MCAR mechanism, for each variable, the complete data can be considered as a random subsample from the intended sample. Moreover, even if we assume that the MCAR assumption holds, deletion of collected data in the complete-case analysis is a waste of information, which is rarely justifiable. Furthermore, if the data originates from a designed balanced experiment, the listwise deletion will create an undesirable unbalanced design.

A different type of complete-case analysis considers the pattern of the observed pattern of missing data and weighs differentially the respondents while still discarding the incomplete cases. The underlying assumption is that the data are MAR. The weights are usually based on poststratification, either direct or based on the response propensity stratification. In the direct poststratification the allocation of the observations to strata is based on the respondents’ recorded values (e.g., geographical or socioeconomic data). For each stratum, given the prior sampling probabilities, respondents’ weights are the inverse of the product of those probabilities and the estimated probability of participation in that stratum. In the consumer satisfaction example, with respondents grouped by the duration since becoming customers, the weight w_k for an observation in the k th group is given by $w_k = 1/(p_k r_k)$ where p_k is the prior sampling probability and r_k is the response rate. In many cases, in the sample design the sampling rates for strata are proportional to the population

rates and equal to the prior sampling probabilities. The corresponding weights will have only to account for the estimated probability of participation in each stratum.

When the weighting is based on the response propensity stratification, the definition of the strata is based on categories of variables (“adjustment cells”) with homogeneous estimated rates of response. The rates of response are estimated by regressing the indicator variable m_i (for response–nonresponse) on the background variables. Little [4] showed theoretically and in a simulation study that when weighting adjustments are employed (in contrast to imputation) adjustment cells based on the response propensity are effective in controlling bias.

Handling of Missing Data – Available-Case Analysis

The listwise deletion method discards information collected in the study and is thus inefficient. The available-case analysis is a relatively simple method to estimate the means and the correlations matrix from all the information available for estimating each parameter separately. Thus, the means of variable Y_k is estimated from all the cases with observed data on the k th variable, while the **correlation** between Y_k and Y_j is estimated from all the cases with observed data on the k th and the j th variable.

The advantage of making use of all the available information is counterbalanced by the fact that the sample base changes from the **estimation** of one correlation to the other, and especially in regression problems, when the data is highly correlated, simulations performed by Haitovsky [5] found that the available data analysis can yield considerably inferior results than the listwise deletion. Later simulations [6] found the available-case analysis superior to the listwise deletion in regression models with weak correlation. Little [1] mentions that the available-case method cannot be generally recommended.

Imputation – Unconditional and Conditional Mean Imputation

Imputation is the replacement of unknown, unmeasured, or missing data with a particular value. As in

the available-case analysis, all the incomplete cases are retained, and the dataset is transformed into a complete (rectangular) dataset by imputing values instead of the missing ones.

The simplest form of imputation is to replace all missing values with the average of that variable. It has been shown that, as expected, the unconditional mean imputation yields inconsistent estimates of parameters both for the variances as well as for the parameters based on the **covariance** matrix (e.g. Affifi and Elashoff [7]). By imputing a single average value for all the missing data, the resulting estimated variance clearly underestimates the actual parameter. Also, the **measures of association** are distorted. For this case as well, Little [1] mentions that the unconditional case imputation cannot be generally recommended.

The conditional mean imputation uses the correlation structure among observed variables. The value imputed for a missing value on a specific variable is the value resulting from the regression prediction equation obtained from the set of complete cases (CCs), with the variable to be predicted as the response variable and all the others as predictor variables. The estimates resulting from the conditional mean imputation improves the estimation of the parameters, which are linear in the data (like regression equations), but can still yield distorted estimates for variances, correlations, **quantiles**, and other parameters, which are not linear in the data.

Imputation – Hot Deck and Predictive Mean Matching

The hot-deck imputation strategy replaces the missing data on one observation with the available data from another matched observation. The method is used by many surveys in the official statistics. Among the versions of hot-deck imputation strategies, the univariate hot-deck strategy is probably still the most commonly used. Under this strategy, given a unit with missing data on one or more items, the method assigns for each variable separately, a value from a record with similar characteristics on the recorded variables. For example, the current population survey (CPS) performed by the Census Bureau [8, 9], use different hot decks for the households, demographic, labor force, industry and occupation, earning, and school enrollment edits. Hot decks are always defined

by age, race, and gender. The hot decks for the major labor force recode (MLR), which classifies adults as either employed, unemployed, or not in the labor force, are defined by age, race, and gender and, on occasion, by a related labor force characteristic. The number of cells in labor force item hot decks is relatively small, perhaps less than 100. On the other hand, the weekly earnings hot deck is defined by age, race, gender, usual hours, occupation, and educational attainment. This hot deck has several thousand cells. David *et al.* [10] compared the performance of the hot-deck imputation in the CPS data to the performance of a structured linear regression model.

The univariate hot-deck strategy handles many imputation problems well but handles more complex problems especially in the multivariate context poorly. One of the main problems is the shrunk correlation when the imputation on each variable is processed individually. As an example, Thibaudeau *et al.* [11] mention the distortion of the multivariate properties of the data obtained by using the univariate hot-deck strategy in the Wealth topical module for the Survey on Income and Program Participation (SIPP). In the sixth wave of the 1996 panel, the correlation coefficient between property value (assets) and mortgage(liability) was 0.39 in the reported (not imputed) data, but only 0.16 in the data imputed by the present univariate hot-deck strategy (i.e., less than half).

The joint hot-deck strategy preserves the correlation between jointly missing data, by imputing two or more items from the same donor. For a unit Y with missing data on several items whose correlation is to be analyzed (say, both assets and liabilities) the joint hot-deck imputation strategy finds a corresponding unit Z which matches Y as well as possible on the items on which both Y and Z are recorded. The missing items in Y are then filled in with the corresponding items in Z . The searching method is sequential. The search starts with all the items, and if no matching unit is found, the search continues for a subset of the most important variables or by reducing the number of categories in variables through collapsing.

The predictive mean imputation and the predictive mean matching can be conceptually considered as extensions to the hot-deck strategies by progressively expanding the number of cells while keeping at least one donor in each cell. In the analyses of paired variables (as assets and liabilities), for each missing observation on one out of the two variables, the

value imputed by the predictive mean imputation strategy is from a donor, such that both the donor and the recipient have matched values on the other variable. On the basis of results of tests performed, Thibaudeau *et al.* [11] suggest replacing gradually the currently used univariate hot-deck strategy in SIPP, first by a bivariate hot-deck strategy for specific pairs of variables, and then by a predictive mean methodology.

The predictive mean matching is a further extension, which selects the donor whose value is to be imputed instead of the missing data on the basis of a distance function rather than directly on the values of the covariates. For each variable Y and based on all other variables, the predictions on Y are computed from the complete data. For a recipient with missing value on Y , the set of potential donors are the units with recorded values on Y . The imputed value by predictive mean matching method is the recorded value of the nearest-neighbor potential donor, as computed from the distance between the donor and the recipient on the predictions on Y . In ordinary predictive mean matching the predictions are computed through a linear regression model.

The methods presented above implicitly assume that the missing data are MAR. Hot-deck procedures and models have been proposed also for cases when the missing data are NMAR. In the hot-deck procedures, instead of imputing the actual donor's value, for the various variables the values may be multiplied by appropriate inflation or factors. By definition, the observed data in a set with NMAR missing do not provide information to allow us to cross-validate the validity of the models' assumption. A cross-validation method that has been suggested and tested is to fit the models under various assumptions and to test the sensitivity of the resulting conclusions.

Multiple Imputation and Bootstrapping

While the biases in estimation caused by missing data are widely recognized, the imputation is not a universally accepted solution. In a glossary of the National Institute of Standards and Technology (<http://ciks.cbt.nist.gov>), it is mentioned that "... imputation is most common in surveys of human populations. It is also used in certain computer experiment applications". Even in "surveys of human populations" the imputation and estimation is not

taken lightly. The international standards code for market, opinion, and social research [12] requires that "... no data shall be imputed/assumed without the knowledge of the project manager. Comparison to the original source data shall be the first step in the process. Any imputation process shall be documented and available to client on request."

It is clear that the imputation raises concern with the practitioners. This concern can be attributed in part to the feeling that imputation is in some sense "inventing data" [1], and that even the sophisticated imputation methods cannot account for all the uncertainty in the actual value of the missing data.

Multiple imputation (MI) developed by Rubin [13] is a practical solution, which can alleviate the problem. For the estimation of an unknown parameter vector Θ , if we have a model for predicting the missing (or erroneous) values conditional on all observed data, we can use this model to make m independent simulated draws for the missing data, each containing different estimated values of the missing values from their predictive distribution. Rubin [13] showed that for a fixed number of draws, $m \geq 2$, the estimate of Θ obtained by averaging the individual estimates is a consistent estimator. Furthermore, a consistent estimate of the covariance matrix can be constructed from the averages of the individual covariance matrices estimated for each draw, and an estimate of the covariance of the estimates between the draws. In particular, the variance of the estimate is the average of the variances from the m draws plus $1 + 1/m$ times the sample variance of the estimates between the m datasets.

The MI can enhance the accuracy of estimated critical values and **confidence intervals** and bands as compared to other methods of dealing with missing data. An additional technique, which was compared in a series of articles with the MIs (e.g. [14]), and which also relies on repeated sampling from empirical datasets and associated estimates is bootstrapping. Both are computationally intensive methods and their development has been supported by the increase in computing **power**. Especially in econometrics, they contribute to the improvement of the estimates of precision of the statistical estimates when standard analytical estimates are biased or even unavailable. Furthermore, the bootstrapping and MIs can be combined, with the **bootstrap** replica being used in the MIs (e.g., Serrat *et al.* [15]).

In a recent industrial design of experiment [16] the bootstrap method was used to impute missing data at **center point** in an industrial **design of experiments**. Indeed, although “imputation is most common in surveys of human populations” the industrial experimental designs are also faced with missing or extra experimental runs, resulting in an unplanned nonrectangular dataset. Imputation can be highly effective in those circumstances.

Despite the concern related to “inventing data” in imputations, both theoretical results and simulation clearly demonstrate that, when performed properly, imputation can considerably improve the accuracy and the efficiency of the analyses. It is our opinion that they probably should be used more often than they are in quality control settings.

Parameter Estimation from Incomplete Data – The EM algorithm

The disadvantage of the imputation techniques mentioned above regarding “invented data” is alleviated in the direct analysis of the nonrectangular, incomplete dataset by the maximum-likelihood analysis. Let us assume that the underlying statistical model whose parameters Θ we have to estimate and the distribution of the data under the model are specified. Furthermore, let us assume that the missing pattern is ignorable, i.e. that in the maximum-likelihood approach, the parameter estimates do not depend on the pattern of the missing values and that pattern can thus be ignored. Little and Rubin [17] called those *ignorable models*.

Under those conditions the expectation-maximization (EM) algorithm [18], is a general and vastly used iterative algorithm, which computes the maximum-likelihoods estimates for Θ and in the intermediate steps performs pseudo-imputations as explained below. Specifically, at the completion of the t th iteration or step of the **EM algorithm**, the current estimated value of Θ is $\Theta^{(t)}$. The expectation step (E-step) $(t + 1)$ th step computes the expected value of the log-likelihood, over the conditional distribution of the missing data Y_{miss} , given the observed data Y_{obs} and the current estimate $\Theta^{(t)}$ of Θ . Now, if the distribution of the data is from the exponential family, the above expectation is equivalent to computing expected values for the sufficient statistics, given Y_{obs} and $\Theta^{(t)}$ [1, 19]. This is the pseudo-imputation

alluded to above. In the M-step of the algorithm, a new estimate $\Theta^{(t+1)}$ of Θ is calculated by maximizing with respect to Θ the expected value of the log-likelihood found in the E-step. The algorithm was proved to converge to the maximum-likelihood estimates of Θ . Since the algorithm was developed, many enhancements, which increase the rate of convergence for various problems with application in industry, have been proposed (e.g. Fessler and Hero [20, 21]).

In many situations, calculating the conditional expectation required in the E-step, may be infeasible. A possible alternative is the stochastic EM algorithm [22] in which the expectations are performed *via* simulation. At the $(t + 1)$ th iteration the missing data is imputed with a draw from the conditional distribution of the missing data given Y_{obs} and $\Theta^{(t)}$. Given the pseudocomplete data, one can maximize the log-likelihood to obtain $\Theta^{(t+1)}$.

The EM algorithm is widely used in a very large spectrum of applications, either in its direct version or in special versions and enhancements developed for particular situations (as the stochastic EM). Among the applications we can mention biomedical imaging, such as positron emission tomography [20, 21, 23, 24] as a robust inference in the multivariate **normal distribution** with missing data [25, 26]; log-linear models for contingency tables with missing data [27]; models for logistic regression with missing covariates [28]; and **survival analysis** with missing covariates [29].

Repeated Measurements in Longitudinal Studies

In the conclusion of this review we return to the example of a longitudinal consumer satisfaction study and present some issues specific to missing data in longitudinal studies. In many such studies (as in consumer satisfaction with a single response or in some clinical studies), the response variable is univariate, with the predictor variables assumed constant over time, and recorded at the baseline. More complex models assume variable predictors, which have to be recorded at each survey time separately. The missing data in longitudinal studies can come in various forms: from the common case of dropouts after one or more initial surveys, to more complex cases of incidental dropouts at no particular order, or even

more complex patterns of missing with unit nonresponse on some surveys and item nonresponse on others. For the sake of simplicity, we focus on the important case in longitudinal studies where the missing data is due to dropout.

The main approaches of dealing with missing data in longitudinal studies are equivalent to those used in single-time studies, with proper and important adjustments. The listwise deletion (or CC) approach performs the analysis on the subset with complete data and ignores the dropouts. The analysis yields valid estimates in the MCAR case, and yields biased estimates in all other cases.

Both single and multiple imputations are used in longitudinal studies. In the clinical trials the entire groups of subjects who started the study are known as the *intent-to-treat* (ITT) group. In those studies, one of the widely used single-imputation techniques (at least until recently) was the last observation carried forward (LOCF) technique. Under this procedure, the observation recorded before the dropout is “carried forward” and imputed for the missing in all subsequent times. LOCF is a model with simple assumptions behind it and it is indeed easy to understand and communicate.

However, the procedure does not give valid analyses if the dropout mechanism is not MCAR. Even then, it can yield biased estimates unless the pattern of response over time is constant, and if groups are compared, the pattern of dropout had to be the same for each group. The LOCF does not give a statistical estimator of any actual population parameter and yields underestimated variances. The procedure was considered conservative (and it is so, but only if a treatment is monotonically beneficial). A frequent argument in its favour is that it can be interpreted as “real world results”. However, this argument is not tenable since the results are likely to be misinterpreted as if they were from marginal inference, and the actual interpretation is very difficult to explain (e.g. Lane [30]). The performance of the procedure was compared in many studies under a variety of simulated types of missingness, and it was found to be under par even under most favorable situations (e.g. [30–34]). Indeed as Carpenter *et al.* [35] and Shao and Zhong [36] put it, “It is time to stop carrying it forward.”

Other single imputations, mentioned in the context of a single-wave study, as the hot deck and the predicted mean imputation are also used in longitudinal studies. Unlike the single-wave studies,

the data used for matching in the hot-deck procedure and for prediction in the predictive mean procedure, include the responses on the previous waves on the same variable.

The MI approach, which was also presented in the context of single-wave studies is effective in longitudinal studies as well. The MI approach carries out analysis under each set of imputation and combines analyses to reflect within-imputation and between-imputation variability. Several techniques involved in MI and used in longitudinal studies are mentioned by Rubin [37], Little and Rubin [38], Schafer and Olsen [39], and Schafer [40].

Assuming ignorable missing data as well as multivariate normal distribution of responses in longitudinal studies, the general mixed model can be used for analyzing the data with or without imputation. The model is also known under the name “mixed model for repeated measures” (MMRM). For the i th unit, $i = 1, \dots, n$, the model for the $(\tau \times p)$ response vector, $\mathbf{Y}_i$ is $\mathbf{Y}_i = \mathbf{X}_i\boldsymbol{\beta} + \mathbf{Z}_i\mathbf{b}_i + \boldsymbol{\varepsilon}_i$, where $\mathbf{b}_i \sim \mathbf{N}_q(\mathbf{0}, \mathbf{D})$, $\boldsymbol{\varepsilon}_i \sim \mathbf{N}_\tau(\mathbf{0}, \boldsymbol{\Sigma})$, and $\mathbf{b}_i$ and $\boldsymbol{\varepsilon}_i$ are statistically independent. $\mathbf{X}_i$ is a $(\tau \times p)$ design matrix for the fixed effects and $\mathbf{Z}_i$ is a $(\tau \times q)$ design matrix for the random effects. $\boldsymbol{\beta}$ is a $(p \times 1)$ vector of unknown fixed effects and $\mathbf{b}_i$ is an unknown $(q \times 1)$ random-coefficient vector (e.g. [41, 42]). Maximum-likelihood estimates for this model (e.g. [43]) can now be calculated either by standard software programs like PROC MIXED in SAS or by more specialized programs like HLM.

If the assumption of nonignorability is considered to be untenable, one can model the dropout as well as the response through selection models (SMs) or pattern-mixture models (PMMs). In the SMs, given the matrix of covariates X , the joint conditional distribution for the responses Y and matrix of missing M is

$$f(Y, M|X, \Theta, \Psi) = f(Y|X, \Theta)f(M|Y, X, \Psi) \quad (3)$$

where the model under no missing data is $f(Y|X, \Theta)$ and $f(M|Y, X, \Psi)$ is the model for the pattern of missing data.

In the PMMs the joint conditional distribution is

$$f(Y, M|X, \Theta, \Psi) = f(Y|X, M, \Theta)f(M|X, \Psi) \quad (4)$$

with the two models coinciding when M is independent of Y . The shortcoming of the models for dropout

is that the model assumptions cannot be tested from the data.

An issue of considerable practical importance is to assess theoretically or in simulations, the performance and robustness of various procedures both in the case when the underlying assumptions are met as well as when they are not met. Thus, one can generate various patterns of missing not at random (MNAR), and assess the robustness of the methods which implicitly assume a MAR mechanism. When the MMRM model is fitted, the fitting may or may not be preceded by a preliminary imputation step.

Several such studies were performed lately. The comparison between LOCF and MMRM [30] led to the conclusion that the use of the LOCF method is likely to seriously misrepresent the results of the study and that LOCF is “not a good choice for primary analysis”. In contrast, except for MNAR cases with substantially unequal dropouts in various groups, the MMRM is unlikely to result in serious misinterpretation. Sensitivity analysis with more complex models is required in dealing with such MNAR patterns of missing data. Simulation results obtained with MMRM, with and without imputations found the MIs to be a valuable technique, and superior to complete-case analysis [44]. The data were simulated under the MAR and MCAR mechanisms. Furthermore, the direct analysis of the incomplete dataset was effective as compared to the imputed data. The effectiveness of adding MIs to the MMRM and to the generalized estimating equations (GEE) was tested recently [45] in a simulated clinical trial setting aimed at determining the treatment effect at specific time epochs. They concluded that in this setting, the additional use of MIs is, in general, counterproductive both in terms of bias as well as in terms of variances.

The imputation procedures and MMRM modeling lately gained acceptance in industry (e.g. [30]). This trend is a positive result of the studies that showed that both imputations (especially MIs) and model fittings are highly beneficial in improving the accuracy of the performed analyses. The benefits to the performed studies far outweigh the shortcomings of the methods, i.e. the fact that imputation seem to be inventing data and the results of MMRM models are more difficult to communicate than analyses based either on CCs or on simple analysis of available data. The trend of increased acceptance of imputation and MMRM model fitting deserves to be encouraged.
